Acknowledgements

I am so grateful to be a part of UTEP geology family. From the first day I started my research here, I have received tremendous amount of help and intellectual input and all the love in the world that make the impossible, possible. This dissertation is the result of hard labor from so many individuals inside and outside the Department of Geological Science. I would like to take this space mention their names, as their hard work should not go anonymous. I would like to give a special thanks to my academic advisor Dr. Jose Hurtado, who never got tired of giving his time to all of his students. My gratitude to all of my committee, Dr. Diane Doser, Dr. Laura Serpa, Dr. Terry Pavlis, and Dr. Efrain Ferrer, for that I have learned so much from them. I give a big bow to my field crews for their assistant and companionship: Victor Avila, Niti Mankhemthong, Ezer Patlan, Ibrahim Cerda, Felix Ziwu, Jose Navarro, Arturo Ramirez, Francisco Torres, Doug Standart, Humberto Garcia, Jackie Clark, Tobgay Tobgay, Jackie Cordova, Matthew Cannon, Perry Houser, Julian Biddle, Anna Mwangi, Alina Valdez, William Seelig, Jenny Gonzalez, Joey Castro, Alexander Traver, Elisa Carrillo, Marc Lucero, and astronaut Reid Wiseman. I also would like to thank you UTEP-Geology staff members: Pamela Hart, Galen Kaip, Carlos Montana, Adriana Perez, and Joel Gilbert whom had dealt a great tedious tasks that makes my fieldwork and academic work goes smoothly. Lastly I am very thankful for my family in Thailand, my mother and sister and for my loving husband for standing by me during these hard years, without them I am nothing.

Abstract

Features such as the Home Plate plateau on Mars, a suspected remnant of an ancient phreatomagmatic eruption, can reveal important information about paleohydrologic conditions. The eruption intensity of a phreatomagmatic volcano is controlled mainly by the quantity of water and magma, the internal geometry of the volcano, and the depth of the interaction zone between magma and water. In order to understand the paleohydrologic conditions at the time of eruption, we must understand all the factors that influenced the phreatomagmatic event. I conducted an integrated geophysical survey, which are magnetic and gravity surveys, and a ground-penetrating radar (GPR) surveys at Kilbourne Hole, a phreatomagmatic crater in southern New Mexico. These investigations serve an analog paleo-hydrogeological study that could be conducted on Mars and the Moon with an implication for planetary exploration. These geophysical surveys are designed to delineate the internal structure of a phreatomagmatic volcano and to define the volumes and masses of volcanic dikes and excavation unit, the depth of feeder dikes, and impacted velocity of the volcanic blocks. For the gravity and magnetic surveys at Kilbourne Hole, I collected data at a total of 171 gravity survey stations and 166 magnetics survey stations. A 2D gravity and magnetic inverse model was developed jointly to map the body of the magma intrusions and the internal structure of Kilbourne Hole. A total of 6 GPR surveys lines were also completed at Kilbourne Hole to image and to define locations of pyroclastic deposits, volcanic sags and blocks, the sizes distribution of volcanic blocks, and the impact velocity of the volcanic blocks. Using the size distribution and impact velocity of volcanic blocks from our GPR data, I derived the initial gas expansion velocity and the time duration of the gas expansion phase of the Kilbourne Hole eruption.

These obtained parameters (volumes, masses, and depths of the feeder dikes and the excavation zone, and the initial gas expansion velocity) are used to quantitatively calculate the mass, volume and condition of groundwater involved in the magma-water interaction process that caused Kilbourne Hole eruption. The joint gravity and magnetic 2D inversion reveals two main bodies of basaltic intrusion dike underneath Kilbourne Hole. The depth to the top of the dike is varied between 0.91 and 3.58 km from the ground surface. The models are able to delineate several complex areas of slumping blocks and collapsed crater, the area of the diatreme and the area of the original crater's excavation. The estimated depth of the diatreme is ~13.6-15.8 km. The model shows that the tuff ring deposits extend 600 m to 1 km away from the crater rim and vary in thickness (50-150 m). Based on our 2D gravity and magnetic inverse models of Kilbourne Hole, we were able to calculate the mass of the magma and the final product of this research, which is the mass of water that fed the Kilbourne Hole eruption. The total mass of the magma (M_m) is 1.38 ± 0.15 x 10^{13} kg and the mass of water (M_w) is (1.09 ± 0.31) x 10^{13} kg. The water to rock mass ratio of the Kilbourne Hole eruption was 0.01-0-02. With the GPR surveys results, we estimate that the initial gas expansion velocity (V_0) of the Kilbourne Hole eruption was 123 ± 9 m/s and the time duration of the gas expansion phase was 92 ± 11 s. The obtained initial gas expansion velocity and the depth of the dikes suggest that the eruption occurred at an initial pressure of 163 ± 9 bar.

I also utilized the lunar gravity field measured by the Gravity Recovery and Interior Laboratory (GRAIL) mission to reconstruct the history of lunar mascon basin formation and magmatic activity. We hypothesize that a combination of uplifted lunar Moho, impact melt sheets, and brecciated crust creates the gravity signature of lunar mascon basins. To test this hypothesis, We performed low-pass and preferential filtering on the free-air anomaly map

derived from GRAIL lunar gravity model GL0660A. Using the preferential filtering method, we isolated the gravity anomalies associated with structures at 16 km and 30 km depth where we can avoid high-frequency gravity signal from the highly impacted subsurface topography and mare basalt. We construct four 2D inversion models from the filtered gravity data to visualize the internal structure of lunar mascon basins. We conclude from our 2D inversion models that the parameters that determine the gravity signatures of mascon basins are: (1) the extent of the impact-melt sheet; (2) the depth to the mantle; and (3) the thickness and density of the surrounding crust.

Chapter 3

Chapter 1: Introduction and Dissertation Overview

The recent discoveries of abundant water on the Moon and Mars (e.g., Cohen and Coker, 2000; Saal et al. 2008; Hauri et al. 2015; Robinson and Taylor, 2014; Anand et al., 2014; Boyce et al., 2014; Furukawa et al., 2014; Robinson and Taylor, 2014; Pendleton, 2015) will have very significant implications for human space exploration. Exploration of the lunar and Martian subsurface would provide critical information about the early history of the Solar System and a critical knowledge of Earth's geological formation. Martian crust probably contains a hydrosphere due to impact fragmentation and processes. Theoretical groundwater models suggested ancient groundwater activity. What does the groundwater system of an early Mars look like? We are not yet certain. The evidence of phreatomagmatic eruptions found on Mars Home Plate indicates the timing when the groundwater and tectonic activity were still active and were actually interacted. We hypothesized that the understanding of the phreatomagmatic volcano's morphology and structure could lead us to the understanding of the groundwater system that fed this particular phreatomagmatic eruption. We have a well-known phreatomagmatic volcanic site locally that could serve well as an analog site. With an implication for planetary exploration in mind, we aim to design a ground-based integrated geophysical survey that could efficiently and perhaps remotely map the internal structure of the phreatomagmatic volcano. We also aim to develop strategies to help us quantitatively interpret paleohydrological condition using a phreatomagmatic volcano as a climate proxy. On the Moon, however, we already have a series of high-resolution gravity and magnetic data from the Gravity Recovery and Interior Laboratory (GRAIL) that were opened for public usage. Instead of purposing a survey designs and approaches, we suggested a methodology to utilize the said data to understand the Moon's internal structure. We found that it is very difficult to interpret the

Moon's high-resolution gravity data, as currently we do not have enough surficial information of the Moon to constrain the gravity model. Without sufficient constraints, geophysical modeling approaches should not be the sole method for resolving unknown geological features. Alternative approaches for resolving the internal structure of phreatomagmatic volcano or mascon basins should also be considered. Currently, the information about the shallow and deep interiors of Mars and the Moon are only derived from low-resolution gravity, magnetospheric, and seismic studies on the Moon. Previous research provided some knowledge about the lunar interior, such as the existence of a liquid core (Williams et al., 2001; Weber et al., 2011) and estimates for crustal thickness (Wieczorek et al., 2006), but most geophysical studies still depend on modeling for interpretation (Williams et al., 2001; Wieczorek et al., 2006; Weber et al., 2011; Zuber et al., 2014). All three of our researches provided an improvement to the traditional modeling approach. For example, we integrated our GPR surveys result and our 2D Gravity and Magnetic jointed inverse model and, we applied the power spectrum depth analysis to constraint the depth of our lunar crustal gravity model.

The primary objective of this dissertation is to design an integrated geophysical method for paleohydrogeological study with an implication for planetary exploration. The product of the primary objectives is the estimated quantity of the groundwater reservoir that fed the Kilbourne Hole eruption. The second objective of this research is to develop a procedure to utilize the high-resolution lunar gravity data GRAIL. The obtained product of the secondary objectives were two detail crustal models of the Moon that reveal the internal structure of type I and type II mascons. We also aim to provide a design of integrated geophysical approaches to geophysical modeling that are easy to conduct and process, while gaining the most information about a planet. We considered several ground-based geophysical survey methods, which are GPR, gravity, and

magnetic that can be performed by a rover and do not rely solely on modeling to investigate internal structures on either Mars or the Moon. This dissertation comprises four chapters. The main focus of Chapters 2 and 3 is Kilbourne Hole, New Mexico, a maar volcano that is a planetary analog to phreatomagnatic eruptioins that may have occurred on Mars and elsewhere. In those chapters, I aim to understand: (1) the geomorphic and internal features of phreatomagmatic volcanoes and how they form in response to hydrologic and volcanic processes; (2) the feasibility of performing ground-based geophysical surveys that include magnetics, gravity, and, GPR to image those geomorphic and stratigraphic features; (3) how shallow subsurface geophysical surveys of a phreatomagmatic volcano can be used to quantitatively estimate paleohydrogeologic conditions at the time of the eruption; and (4) how geophysical methods might be employed on other planets, such as Mars and the Moon. In Chapter 4, I: (1) develop a power spectrum analysis and preferential filtering method that can be used to isolate the gravity signal of a specific depth for 2D modeling; and (2) provide a quantitative interpretation of lunar crustal structure and mascon basins using a 2D gravity inversion method.

The products of this dissertation are three manuscripts intended for publication, first of which is centered on magnetic and gravity methods (Chapter 2), second of which is centered on the GPR method (Chapter 3), and the third will focus on the preferential filtering and inverse modeling of the Moon's free air gravity anomaly (Chapter 4). Chapter 2 describes the design of magnetic and gravity surveys at Kilbourne Hole, the data collection scheme, and the construction of a joint 2-D inverse model that is used to delineate the internal structure, thicknesses, and volumes of the eruptive units around Kilbourne Hole as well as the depth of the buried feeder dikes below Kilboune Hole. The inversion process is constrained by the thicknesses and types of

pre-eruptive lithologies, the topography of the area, magnetic susceptibility, and density. Several best-fit joint inversion models for Kilbourne Hole were used to estimate the parameters needed for paleohydrological study. These parameters include the volume of ejected pyroclastic material and the volume and the depth of the feeder dikes. These parameters are used to calculate the changes in internal heat energy, potential energy, and kinetic energy needed to solve for the gas-to-magma mass ratio and the amount of groundwater at the time of eruption. In Chapter 3, I present the results of a GPR campaign at Kilbourne Hole. Six GPR profiles oriented radially with respect to the center of the crater were performed. The goal of the GPR campaign was to map the size distribution of volcanic blocks as a function of distance from the crater in order to derive the maximum gas expansion velocity of the eruption (V_0). This velocity is used to calculate the kinetic energy of the eruption, a quantity that is related the amount of water involved in the eruption. Knowing this velocity is essential to constraining the amount of water in the eruptive system. Chapter 4 describes the application of modeling of GRAIL mission data to determine lunar crustal structures and the formation of mascon basins. Prior to inversion modeling of the free-air gravity anomaly, we also first applied a low-pass filter and the preferential-filtering method (Spector and Grant, 1970; Guo et al., 2013) to remove the high frequency gravity signal from the free air gravity data and selectively filter the gravity signal from the depths of 16 km and 30 km. We also applied a power spectrum depth analysis method (Spector and Grant, 1970; Guo et al., 2013) to constrain the depth result of our inversion model. Our 2D inversion models provided the quantitative interpretation of lunar crustal structure and mascon basins which are: (1) the extent of the impact-melt sheet; (2) the depth to the mantle; and (3) the thickness and the density of the crust surrounding mascons.

Abstract

Features such as the Home Plate plateau on Mars, a suspected remnant of an ancient phreatomagmatic eruption, can reveal important information about paleohydrologic conditions. The eruption intensity of a phreatomagmatic volcano is controlled mainly by the quantity of water and magma, the internal geometry of the volcano, and the depth of the interaction zone between magma and water. In order to understand the paleohydrologic conditions at the time of eruption, we must understand all the factors that influenced the phreatomagmatic event. We mapped the internal structure of a well-known phreatomagmatic volcano, Kilbourne Hole in southern New Mexico, in order to quantify the mass of the dike (m_m) and volume of the diatreme (V_{dia}), the depth of the magma source (h), the mass of pyroclastic material (m_f), and the volume of excavated crater (V_{exc}) of the Kilbourne Hole structure. We then calculated the amount of groundwater that fed the volcanic system using these quantities (h, m_m, m_f, V_{exc}, V_{dia}). A phreatomagmatic volcano produces very explosive eruptions and a very deep volcanic structure rooted into the pre-eruptive rock formation. The juxtaposition between volcanic structures and the pre-eruptive rock formation make gravity and magnetic surveys an appropriate method for this purpose. To quantitatively estimate the masses and volumes of Kilbourne Hole phreatomagmatic deposits, we must quantitatively define the geometry of all the units of

Kilbourne Hole phreatomagmatic deposits; we performed a 2D inversion modeling from both of our gravity and magnetic surveys at Kilbourne Hole. Inverse modeling of the gravity and magnetic data reveals three basaltic dikes beneath Kilbourne Hole. The depth below the pre-eruption ground surface to the top of the dikes varies: dike 1, on the eastern rim of the crater, is 1.75-2.25 km deep; dike 2, beneath the center of the crater, is 0.91-3.58 km deep; and dike 3, beneath the western rim of the crater, is 0.14-2.50 km deep. The inverse models are also able to delineate several complex areas of slump and rotated blocks associated with crater collapse, the diatreme, and post-eruption fill units within the crater. The estimated total depth to the bottom of the diatreme is 13.6-15.8 km from the pre-eruption surface. The tuff ring deposit around the crater extends 600 m to 1 km away from the crater rim and our inverse model shows that it varies in thickness between 50 and 150 m. Based on the geophysical models we have developed for Kilbourne Hole, we estimate the mass of the magma (m_m) related to the Kilbourne Hole eruption to be (1.38 ± 0.15) x 10^{13} kg and the mass of water (m_w) to be (1.09 ± 0.31) x 10^{13} kg, for a water-to-magma mass ratio of 0.79 ± 0.23.

Keywords: phreatomagmatic volcano, gravity, magnetics, Kilbourne Hole, planetary geophysics, groundwater, paleohydrology, tilt angle derivative, 2D inversion, Mesilla basin, Rio Grande rift

1. Introduction

Phreatomagmatic eruptions occur when groundwater comes in contact with magma in the subsurface. The heated water will flash into steam, which, if confined, will build up pressure, potentially to the point of explosive release. The resulting explosion will excavate a crater and eject pyroclastic material (Wohletz and Sherridan, 1981). The efficiency of resulting explosion is determined by the ratio between the mass of water to the mass of magma that fed the eruption system (Wohletz, 1986). The size and volume of pyroclastic deposits from a phreatomagmatic eruption is a function of the amount of groundwater in proportion to the amount magma. The study of the internal structure of a phreatomagmatic volcano can lead us to an understanding of the amount of groundwater present prior to the eruption. By quantifying the volume of the pyroclastic deposit from a phreatomagmatic eruption, we can also quantifying the amount of groundwater interacted with the magma source at the time of eruption. This chapter focuses on the results of our ground-based gravity and magnetic study at a well-known phreatomagmatic volcano – Kilbourne Hole in New Mexico – designed specifically to decipher the paleohydrogeological conditions at the time of eruption. The present geological setting of Kilbourne Hole is similar to Martian volcanic terrain. The surface of Kilbourne Hole is covered with 50 -150 m thick of tuff ring and pyroclastic deposit. Underlain the pyroclastic deposit is the Aden and Afton basalt flow layer. The techniques used in this research can serve as an analog for ground based gravity and magnetic surveys that can be applied to paleohydrologic exploration of other planets such as Mars. The main implications of this combined application for the exploration of Mars are: (1) our field survey methods; (2) the methodology used to process the gravity and magnetic data to reveal the internal structure of Kilbourne Hole, specifically to allow us to map the extent and volume of ejected pyroclastic material and the size and shape of the

magma body that triggered the eruption; and (3) an estimate for the amount of groundwater present at the time of the Kilbourne Hole explosion.

Both magnetic and gravity surveys are non-invasive, portable and easy to process. They are also passive methods that do not need probe, electrode or any energy to be inserted into the ground in order to acquire data; this makes the magnetic and gravity method operable by a rover and is suitable for a remote setting such as Mars or the Moon. Here we provided a design of gravity and magnetic surveys that were used specifically to delineate all shapes and sizes of the internal features of a phreatomagmatic volcano. We also provided an adaptation of an integrated 2D modeling of gravity and magnetic data to quantitatively interpret and map the internal features of a phreatomagmatic volcano. The internal structures of phreatomagmatic volcanoes are very complex. The eruptions of phreatomagmatic volcanoes are catastrophic and chaotic; following the mass removal process is the caldera-like collapsing of the crater, resulting in several fault zones and rotated fault blocks that overlap and superimpose upon one another with no extinctive bedding. This makes it very difficult to extract and delineate geo-anomaly signals of this kind of landform. The gravitational anomaly from this complex feature of the phreatomagmatic crater may not be differentiated under the traditional assumption and interpretation. Therefor in addition to traditional gravity anomaly interpretations and 2D modeling, we apply a nonlinear method called a tilt-derivative method to our gravity and magnetic data (Miller and Singh, 1994) to define edges and geometry of the buried pyroclastic formation. The result of integrated 2D modeling of gravity and magnetic data can successfully resolves complex structures of a phreatomagmatic eruption at Kilbourne Hole including: 1) excavation zone due to the mass removal process of eruption, 2) rotated blocks of pre-eruptive rocks buried inside the vent due to is the collapsing of the crater, 3) several fault zones created

by the collapsing of the crater, 4) dikes, 5) diatreme or the brecciated rocks that filled in the volcanic vent, and 6) surrounding tiff ring. We demonstrated in this chapter the conduction of our field surveys and the steps we used to extract gravity and magnetic anomalies that reveal the internal structures of Kilbourne Hole. Lastly, we then demonstrate how we determine the eruption efficiency and the relationship between the mass of magma and the mass of water that fed the eruption and how to quantifiably interpret the related groundwater that caused the phreatomagmatic eruption of Kilbourne Hole. While GPR (Chapter 3) will be used to map the shallow subsurface structures of volcanic blocks and sags, gravity and magnetic surveys (Chapter 2) provided diagnostic information about the deeper subsurface lithology, shape, and structures of the diatreme, deep intrusion zones, and its regional geology.

2. Study Location

Kilbourne Hole is a well-known phreatomagmatic volcanic crater located in Southern Doña Ana County, New Mexico, in the Mesilla basin at the southwest margin of the Rio Grande rift (Figure 1). This maar crater is a 2-km wide, 200-m deep depression (Reiche, 1940). The Kilbourne Hole eruption occurred during the mid-Pleistocene (0.02-0.1 Ma; Seager, 1984). Seager (1984) and Lorenz (1973) suggested that the excavation of Kilbourne Hole was caused by catastrophic subsidence, similar to caldera collapse, following phreatomagmatic explosive activity.

The Rio Grande rift and the series of basins related to it are major tectonic features of the North American continent that extends from Colorado, through New Mexico, and into northern Chihuahua, Mexico, covering a distance of about 950 km (Ramberg et al., 1978; Keller et al., 1990). The extension that formed the Rio Grande rift, and the associated volcanism, began about 30 million years ago (Ingersoll, 2001) and still continues today (Keller et al., 1990). Volcanic activity has occurred throughout the Rio Grande rift (Lipman, 1969). During the Pliocene to Quaternary, volcanic activity in the Rio Grande Rift mostly erupted alkali-olivine basalt and, in some localities, tholeiitic basalts (Keller et al., 1990). This variation in composition indicates that magmas have been derived from various depths, with tholeiitic basalts originating at shallower depths than alkalic basalts (Lipman, 1969).

The Mesilla Basin is bound on the east by the Organ, Franklin, and Sierra de Juarez mountains, and on the west by fault-block and volcanic uplands that extend northward from the East Potrillo Mountains and West Potrillo basalt field to the Aden and Sleeping Lady Hills (Figure 2). Prior to the Kilbourne Hole eruption, there were already series of volcanic flows in the vicinity of Kilbourne Hole (Seager, 1984). This volcanic flow series is called the Potrillo

volcanic field. The central area of the Potrillo volcanic field is covered by a series of three to five lava flows that erupted from Aden and Afton craters (Hoffer, 1972). Below the Afton-Aden basalt flows is the Late Quaternary (2-3 Ma) Santa Fe group (Figure 2). The Santa Fe group is a 1.5-2-km thick package of fluvial sediments deposited by the ancestral Rio Grande River (Seager, 1984). There are two parts of the Santa Fe group. The younger unit is the Camp Rice Formation, which contains fluvial and piedmont sediments (Lorenz, 1986). The older unit is the Fort Hancock formation, which contains alluvial sediments (Hawley, 1975).

The Kilbourne Hole explosion excavated through both the Santa Fe group and the overlying Afton-Aden basalt flows. Both pre-eruptive units can be seen exposed inside Kilbourne Hole. The Kilbourne Hole explosion deposited 50-150 m of air-fall and pyroclastic surge deposits around the crater rim (Lorenz, 1986). Pieces of alkali olivine can be found within the pyroclastic deposits, indicating that there was a basaltic intrusion located underneath Kilbourne Hole (Hoffer, 1972; Hawley, 1975). The pyroclastic deposits can be traced 800-1000 m radially away from the modern crater rim (Seager, 1987). There are two sets of pyroclastic layers: one that was deposited as a tuff ring around the crater rim, and one that has collapsed into the crater (Figure 3). The dips of both sets of pyroclastic strata range from 8° to 35° (Seager, 1987). After the Kilbourne Hole eruption, aeolian and fluvial sediments were deposited throughout the area, including the interior of Kilboune hole, and these deposits mantle all of the older units (Figure 3).

3. Background

3.1 Hydrology and Physics of Phreatomagmatic Eruptions

A phreatomagmatic eruption is a kind of volcanic eruption caused by the explosive interaction between rising magmas and external sources of water, such as an aquifer or surface water (Wilson and Head III, 2003). The resulting eruptive phenomena include pyroclastic flows, debris flows, air fall tephra, and the ejection of volcanic blocks (Barberi et al., 1989). Landforms produced by phreatomagmatic eruptions include an excavated crater, called a maar, and the surrounding tuff ring or cone (White and Ross, 2011).

The relationship between the amount of water and the resulting explosive eruption was established by Wohletz and Sheridan (1981) based on a comparative study of the geomorphology and stratigraphy of eleven basaltic phreatomagmatic volcanoes. A tuff ring (pyroclastic deposit with 0°-10° dips) is formed from an explosion at a shallower depth than a tuff cone (pyroclastic deposit with 10°-25° dips). Wetter eruptions can result in larger diameter tuff rings and tuff cones (Wohletz and Sheridan, 1981). Based on their observations, Wohletz and Sheridan (1981) suggested that fluid-dynamic interactions between groundwater and the melt could affect the strength of the resulting explosion. The existence of fluid in the eruption process forms a large crater and creates a remarkably high-volume of ejecta, including pumice, ash flows, and airfall (Wilson and Head, 1994).

Most of the empirical research to quantify water-magma interactions has been done by Wohletz and Sheridan (1981; 1982; 1983; 1989) using a water tank and thermite to simulate the groundwater reservoir and magma, respectively. These experiments have investigated the

parameters that describe the characteristics of phreatomagmatic eruptions. We highlighted which parameters we could obtain using gravity and magnetic methods.

When magma contacts groundwater, a large amount of heat is exchanged between the magma and the water. Water's high specific heat index effectively converts thermal energy into mechanical energy (Self and Sparks, 1978). In a phreatomagmatic explosion, typically only a small percentage (<10%) of the magmatic heat is converted to explosive energy, most likely because the magma and water do not mix well (Wohletz, 1986).

The process of magmatic heat exchange of a phreatomagmatic eruption can be explained using thermodynamics of an open system (Wohletz, 1986). An open system in thermodynamic is when there is an exchange of energy (heat and work) between the system and their environment. A boundary allowing energy exchange between the system and their environment must be permeable. To explain the eruption process of Kilbourne Hole using thermodynamics, we make these following assumption: (1) the system of a phreatomagmatic eruption is where the crater were excavated. The volume of the system (V_{sys}) is equivalent to the volume of fragments and water vapor that were ejected from the crater (V_{exc}), (2) the permeable environment that allows heat to transfer to the system is the crater vent filling sediment that lies between the magma (dikes) and the system. The volume of the permeable environment is equivalent to the volume of Kilbourne Hole's vent excluding the volume of the dike or the volume of the diatreme (V_{dia}).

Another parameter used in thermodynamics to explain the phreatomagmatic eruption is thermal efficiency. The thermal efficiency of an eruption indicates how much heat is converted to energy output. The efficiency of the eruption can be quantified by the conversion rate (CR) between the change in thermal energy (ΔU) and the change in work done to the system (ΔW_{sys}) (Wohletz, 1986).

$$CR = \frac{\Delta W_{sys}}{\Delta U} = \frac{\Delta W_{exc}}{\Delta U} \quad (1),$$

where ΔU is the change in magmatic thermal energy and ΔW_{sys} is the change in work done to the system. ΔW_{exc} is the change in work done to the excavation zone of the volcano.

The change in thermal energy is result of heat exchange between the magma and pore water. The amount of change depends on the mass of magma, heat capacity of magma, and the associated temperatures. A mass of basaltic magma, m_m, at an absolute temperature (T_m) of 1493 K (Wohletz, 1986) comes in contact with a mass of external water, m_w, at an absolute temperature (T_w) of 298 K. The amount of change in thermal energy from the magma intrusion at Kilbourne Hole is (Wohletz, 1986):

$$\Delta U = m_m C_{vm}(T_m - T_e) \quad (2).$$

where m_m is the mass of magma, C_{vm} is the specific heat of the magma at constant volume (C_{vm} = 1 kJ kg^{-1} K^{-1}; Wohletz, 1986); and T_e *is* the ideal equilibrium temperature (298 K; average Earth surface temperature).

In the first stage of the eruption, magmatic thermal energy is converted into the change in work done to the system. The total energy in the system is partitioned between the change in kinetic energy of the excavated fragments and released water vapor (ΔKE), the potential energy of the excavated fragments and released water vapor ($p_0 V_{exc}$), and the change in potential energy inside the diatreme (ΔPE_{dia}) (Wohletz, 1986).

The total energy in the eruption system (Δ_{excs}) is:

$$\Delta Wsys = \Delta \mathrm{KE} + \Delta PE_{dia} + p_o \Delta V_{exc} \quad (3),$$

where ΔKE is the change in kinetic energy of the excavated fragments and released water vapor, ΔPE_{dia} the change in potential energy inside the diatreme, and $p_0 V_{exc}$ is the potential energy of the excavated fragments and released water vapor.

In the second stage of the eruption, the system expands isentropically into atmosphere (Wohletz, 1986). The change in kinetic energy of the excavated volcanic fragments and released water vapor is equal to:

$$\Delta KE = \frac{1}{2}(m_f + m_w)\, v_{max}^2 \qquad (4),$$

where v_{max} is the maximum velocity of the excavated fragments and released water vapor, and m_w and m_f are the masses of water and volcanic fragments, respectively, that are released from the eruption. The mass of water is unknown, and it is the goal of this research to estimate it. The mass of the volcanic fragments can be estimated using gravity and magnetic data as we show in this paper. Similarly, v_{max} can be derived from geophysical data, specifically by measuring the clast size distribution of ejected volcanic blocks using ground-penetrating radar (GPR) (Rhodes and Hurtado, 2014; v_{max} = 113.46-132.21 m/s; see Chapter 3).

Prior to the expansion of volcanic gas, the diatreme were under a litho-static pressure that is equal to the weight of the material above the interaction zone between water vapor and magma source. The confined pore water inside the diatreme was heated by magma intrusions. Explosive eruptions are thought to initiate when: (1) magma comes in contact with external water; and 2) pore fluid pressure overcomes the tensile strength of the rock above the dikes (Spieler et al., 2004; Mueller et al., 2008). The pore fluids can develop super-pressured condition when permeability inside the diatreme increases rapidly (Rubey and Hubbert, 1959a). The increasing of permeability inside the diatreme can be a result from hydrofracturing or explosive brecciation

of the rocks, or fault ruptures (Rubey and Hubbert, 1959a). We are not certain whether the eruption of Kilbourne Hole ever developed a super-pressured condition or not. From our mode, there are several faults found at the location of Kilbourne Hole. Although with the extension mechanism along the edge of Rio Grande Basin those faults zone is the pre-existing rifting and faulting, not involving with super-pressured condition.

Day (1996) confirmed that the reduction in strength of volcanic materials is due to the effect of high pore pressure relative to confining pressure. This can be expressed as the ratio, λ, of the pore pressure to the confining pressure. In a phreatic eruption, pore fluid pressure is equal to litho-static pressure (λ = 1). If the eruption occurs in super-pressured conditions, in which fluid pressure is sufficient to cause tensile failure of rock, then λ >1. Pore pressure as a fraction of litho-static load in super-pressured condition is:

$$\lambda = 1 + \frac{\tau_o}{p_1} \qquad (5),$$

where p_1 is the litho-static load pressure at the depth of rupture, and τ_o is the cohesive strength of rock or the cohesive strength of a pre-existing fracture (generally very small or zero). We can calculate the litho-static load pressure at the depth of rupture using the information derived from our model which are the density of rocks that are the litho-static load, the cross-sectional area of the excavation. Our model is able to reveal the location and the depth where magma interacted with the litho-static load. The eruption of Kilbourne Hole occurred when the pore pressure inside the diatreme became equal to the litho-static load pressure. We can calculate the litho-static load pressure (p_1) inside the diatreme of Kilbourne Hole as follows (Athy, 1930):

$$p_1 = \rho g h \qquad (6),$$

assuming that gravitational acceleration (g) is a constant with depth (h) and where ρ is the density of the overlying rock at depth h. Our integrated gravity and magnetic models of Kilbourne Hole can be used to reveal the depth of the litho-static load. The density of the litho-static load should be a weighted average density of all geological material included in the litho-static load. The litho-static load at Kilbourne Hole: (1) Camp Rice formation with a density of ~2560 kg/m^3; and (2) Aden basalt with a density of ~3100 kg/m^3.

Immediately before the eruption, prior the brecciating of the diatreme and the rupture of the volcanic system, the potential energy was being stored inside the diatreme in the form of increasing pore pressure. The change in potential energy, ΔPE_{dia}, of the Kilbourne Hole's diatreme, the releasing of potential energy initiate and sustain the fragmentation process, is provided by the expansion of the pressurized gas trapped in the pore space of the diatreme material. ΔPE_{dia} can be written as:

$$\Delta PE_{dia} = p_1 V_{dia} \qquad (7),$$

where V_{dia} is the volume of the diatreme (Wohletz, 1986). Because this pressure increases with depth, the depth at which the magma and groundwater interact is an important control on the litho-static pressure and on the resulting power of the eruption.

The third term of Equation (2) ($p_o \Delta V_{exc}$) is the result of the change in the volume of the system after rock fragments and water vapors were excavated at the time of the eruption, where p_o is the pressure of the system at the final stage of eruption and V_{exc} is the change of the volume in the volcanic system. To estimate the final-stage pressure of the eruption, we assume that towards the latter stages of eruption the pressure of the system was close to atmospheric pressure at the time prior the eruption. The atmospheric pressure is 0.89 bars at 1.22 km elevation above

the sea level, the estimated elevation of the pre-eruption surface (the top of the Aden basalt) (NOAA, 1976). We use 0.89 bars as the final stage pressure (p_o) for the Kilbourne Hole eruption. The results of our gravity and magnetic models of Kilbourne Hole can be used to determine V_{exc}. We define V_{exc} to be the sum of: (1) the volume of the unfilled crater; and (2) the volume of the alluvium inside the crater.

By substituting Equations (2)-(7) into Equation (1) we obtain:

$$CR = \frac{\frac{1}{2}(m_f + m_w)v_{max}^2 + p_1 V_{dia} + p_0 V_{exc}}{(M_m C_{vm}(T_e - T_m)} \quad (8).$$

This can be rearranged to solve for the mass of groundwater (m_w):

$$m_w = \frac{2\,(CR.m_m C_{vm}(T_m - T_e) - p_1 V_{dia} - p_0 V_{exc})}{v_{max}^2} - m_f \quad (9).$$

In order to determine the mass of groundwater using Equation (9), we must define the mass of the melt (m_m), the volume of excavated fragments (V_{exc}), the total volume of the diatreme (V_{dia}), and the maximum ejection velocity of volcanic blocks (v_{max}). In this paper, we describe how to determine the masses and volumes using magnetic and gravity surveys. In Chapter 4, we describe how to determine v_{max} using ground-penetrating radar (GPR).

3.2 Eruptions Efficiency and Gas to Magma Mass Ratio

The explosive energy of an eruption can be expressed in terms of eruption efficiency, which is quantified as the ratio of thermal energy to mechanical energy (Wohletz, 1983). The mechanical energy results from the flash vaporization of water due to rapid superheating (Wohletz, 1983). The mechanical energy is then partitioned among fragmentation energy,

kinetic energy, seismic energy, and acoustic energy. The efficiency of this eruption process is dominantly a function of the mass of the melt, the mass of the water, and the confining pressure in the zone where the melt and water interact (Wohletz, 1983). Thermal energy results from the heat transfer between magma and liquid water. The thermal energy is proportional to the heat capacity of liquid water, mass of water that was in contact to the magma body, and the temperature difference between liquid water and magma (Wohletz, 1983).

Sheridan and Wohletz (1981) outlined the factors that control the energy of phreatomagmatic eruptions using the results of prior observation (Fuller, 1931; Jaggar (1949; Wohletz, 1983) of the 1924 eruption of Kilauea Volcano on several individual fall and surge and sand wave beds. Figure 2 plots eruption efficiency versus water-to-melt mass ratio as determined from experimental and field studies (i.e., Wohletz and McQueen, 1981; Wohletz and Sheridan, 1982). The curve in Figure 2 can be subdivided into regions: Strombolian activity (mass ratio of 0 to 0.1); Surtseyan activity (mass ratio of 0.1 to 1.00); and submarine extrusion of pillow basalts (mass ratio >3.00). Phreatomagmatic water vapor explosions occur at mass ratios near 0.1 and reach a maximum mass ratio near 0.3 (Wohletz and Sheridan, 1982). A mass ratio of 1.0 produces pyroclastic surges of dry, superheated steam that deposit dune or sandwave beds (Wohletz and Sheridan, 1982). Ratios above 1.0 result in wet, condensed steam eruptions that deposit massive pyroclastic surge and flow beds (Wohletz and Sheridan, 1982). Such deposits commonly are associated with accretionary lapilli, lahars, and soft-sediment deformation (Wohletz and Sheridan, 1982).

The kinetic energy of an eruption is in the form of pyroclastic material moving away from the vent. At the moment of eruption, the potential energy associated with the accumulated gas pressure is converted to kinetic energy (E_k) (Zimanowski et al., 1995):

$$E_k = \frac{1}{2}(M_f + M_w)V_0^2 \qquad (5),$$

where M_f is the mass of pyroclastic fragments and M_w is the mass of water. By knowing the kinetic energy, the maximum velocity of the gas (water vapor) and the pyroclastic fragments, and the mass of pyroclastic fragments, we can solve for the mass of water in the system.

4. Methodology

4.1 Magnetic and Gravity Surveys

A magnetic survey was performed during March 2011 and May 2011 to map the subsurface magnetic anomalies within and around Kilbourne Hole. A single-sensor G858 cesium-vapor magnetometer was used to make measurements at a total of 166 stations arranged in a grid with a 200-m grid spacing that covers the entire crater (Figure 4). All the measurements were tied to three base stations that were set up along the three corners of the crater (Figure 4). The magnetic base stations were reoccupied every 2-3 hours during the survey and at the beginning and at the end of each survey day.

A gravity survey was performed at Kilbourne Hole during June 2013 and November 2014. A Lacoste and Romberg G30 gravimeter was used to make a total of 172 gravity measurements at the same stations where the magnetic measurements were made, along with an additional 6 measurements. Precise elevations for each gravity station were measured using a Topcon GB-1000 real-time kinematic (RTK) differential GPS unit. The RTK surveys provided a horizontal accuracy of ±10 mm and a vertical accuracy of ±15 mm. All the gravity measurements were tied to same three base station locations used for the magnetic survey (Figure 4) and to the absolute gravity geospatial base station located at John W. Kidd Memorial Seismological Observatory at The University of Texas at El Paso (http://www.gis.utep.edu/subpages/states/documents/Texas/DESC.EL_PASO_A.pdf). The gravity base stations were reoccupied every 2-3 hours during the survey and at the beginning and at the end of each survey day.

4.2 Gravity and Magnetic Data Corrections

Prior to modeling, magnetic data must be processed and corrected for diurnal geomagnetic field fluctuations, the magnetic field background at the latitude of the survey, the polarization of rock formations in the area, and noise sources such as thunderstorms or electrical wires. Kilbourne Hole is far away from cultural noise, and Kilbourne Hole is relatively young to have been effected by magnetic field reversal or polarization of the magnetic field in the rock. Therefore we only corrected our magnetic data for the diurnal geomagnetic field fluctuations and the magnetic background at the latitude of Kilbourne Hole. The diurnal correction is done by comparing the location and time of each magnetic measurement to measurements taken at a base station. To correct for magnetic background, we use the total magnetic field intensity from the International Geomagnetic Reference Field as adopted by the International Association of Geomagnetism and Aeronomy (Finlay et al., 2010). In addition to these corrections, we also performed a reduction-to-pole operation to recalculate the total magnetic intensity data as if the inducing magnetic field had a 90^{o} inclination (Bankey et al., 2002). This transforms dipole magnetic anomalies to monopole anomalies centered over their causative bodies, which can simplify the interpretation of the data. Our reduction-to-pole magnetic data and its coordinates are included in Appendix A.

For the raw gravity data collected from Kilbourne Hole, we followed the correction process described in Briesacher at el. (2002) to make our field data compatible with the regional southwestern North American gravity data in the GEONET database (Hildrenbrand et al. (2002); Appendix B). Terrain corrections were calculated using a digital elevation model and a technique implemented in *Geosoft 7.0* (Nagy, 1966). We used the digital elevation model Kilbourne Hole 32106a6 with a resolution of 1/3 arc second (~10 m). Latitude and longitude

values are referenced to NAD27 (North American Datum 27) and elevation values are referenced to the NGVD88 geodetic vertical datum (USGS, 2009). The weight of the atmosphere can affect the gravity measurements, and, because of this, we also performed an atmospheric correction to our gravity data. The correction varies from 0.87 mGal at the ellipsoid to 0 mGal at about 34 km above the ellipsoid (Moritz, 1980).

After we performed the terrain and atmospheric corrections to our gravity data, we performed the free-air and Bouguer corrections. To correct for the decrease in gravity with height above the ellipsoid, we employed a free-air correction with a second order height correction (Heiskanen and Moritz, 1969; Li and Gotze, 2001). To correct for the gravitational attraction of the mass between each station, we performed the Bouguer correction. Because of the small size of our survey area (~10 km^2) we employed a horizontal infinite slab Bouguer correction instead of a spherical cap correction. Our Bouguer correction uses the following constants (Mohr and Taylor, 2001): spherical Earth radius of 6371 km; crustal density of 2,670 kg/m^3; and Newtonian gravitational constant of $(6.673 \pm 0.01) \times 10^{-11} m^3\ kg^{-1}\ s^{-2}$. Our corrected gravity data and its coordinates are included in Appendix B

4.3 Tilt Angle Derivatives and Edge Detection

After the correction of gravity and magnetic data, we can then plot gravity and magnetic anomaly maps (Figure 4). Based on the gravity and magnetic anomaly maps of Kilbourne Hole, we can make qualitative interpretations about subsurface features that may being contributing to the high and low value anomalies present in the maps. To acquire quantitative interpretation of both gravity and magnetic anomalies using the inverse modeling method, it would be beneficial

to have had *a priori* knowledge about the dimension of a source that contributed to the anomaly (Paterson and Reeves, 1985). In this research we used the inverse modeling method to quantitatively interpret our gravity and magnetic anomaly maps of Kilbourne Hole.

Euler deconvolution is a computational process used in the inversion method. It was first presented by Thompson (1982) and is widely used to interpret magnetic and gravity data. The main advantage of Euler deconvolution in inversion modeling is that it can provide an estimated location and shape for source bodies. The disadvantage of the Euler deconvolution for inverse modeling is that it requires an assumption to be made about the geological properties of the model bodies. Another disadvantage is that the result of Euler deconvolution can be non-unique and must be constrained with *a priori* data. We can constrain our inverse models using known ranges of rock density and magnetic susceptibility, and the size, depth, or geometry of the geological features. However, even with a well-constrained model, non-uniqueness is still a problem.

In addition to inverse modeling using Euler deconvolution, we also use the tilt-angle derivative technique to define the shape and edges of the gravity or magnetic anomaly (Miller and Singh, 1994; Verduzco et al., 2004). The tilt angle derivative of a magnetic or gravity source can define the edge of the anomaly in a way that is relatively insensitive to the depth of the source and, as a result, it can resolve shallow and deep sources equally well (Miller and Singh, 1994). Our gravity and magnetic anomaly map of Kilbourne Hole contains sources from both shallow and deep sources. To resolve for both shallow and deep sources and to constrain our model with known geometry, we use the tilt angle method (Miller and Singh, 1994).

This tilt-angle derivative method yields an estimated location of the anomaly and geometry of the source without any *a priori* data. The example given here is for the case of a

magnetic field anomaly, the tilt angle derivative in the vertical direction is (Miller and Singh, 1994):

$$\theta = \tan^{-1}\left[\frac{\frac{\partial M}{\partial z}}{\frac{\partial M}{\partial h}}\right] \qquad (10),$$

where:

$$\partial M/\partial h = \sqrt{\left(\frac{\partial M}{\partial x}\right)^2 + \left(\frac{\partial M}{\partial y}\right)^2} \qquad (11),$$

And $\partial M/\partial x$ and $\partial M/\partial y$ and $\partial M/\partial z$ are the first-order derivatives of the magnetic field *M* in the *x*, *y* (x and y are map coordinates expressed in terms of horizontal distance) and *z* (z is the depth of the signal expressed in terms of wave number). Equation (10) expresses a tilt angle derivative in term of radians and the value of the tilt angle derivative always will be between $-\pi/2$ and $\pi/2$. To implement tilt angle derivative method and compute the tilt derivative from our gravity and magnetic data, we used the tilt-angle derivative function (`tiltdrv.gx`) implemented in *Geosoft Oasis Montaj 6.2*. The tilt angle derivative equation for the gravity field is similar to the tilt angle derivative equation for the magnetic field; only the main variable would be ∂G (gravity field) instead on of ∂M (magnetic field).

The tilt angle method can also enhance deep anomalies by adjusting the anomalies with the ratio of the vertical derivative of gravity or magnetic anomaly to the horizontal derivative of gravity or magnetic anomaly (Miller and Singh, 1994). If the gravity or magnetic source is deep, the vertical derivative will be positive, resulting in a positive tilt angle (Miller and Singh, 1994). If the gravity or magnetic source is shallow, the vertical derivative will be negative, resulting in a negative tilt angle (Miller and Singh, 1994). At the edge of a gravity or magnetic anomaly, there is no change in the horizontal derivative, resulting in a tilt angle of zero. With the tilt angle

derivative method in Figure 5, we can then enhance the area of the gravity and magnetic anomaly from the deeper layers, and we can also identify the edge of the anomaly. Knowing the edge of the anomaly can provide us geometry of the geological features that can constrain our inversion model.

4.4 Two-Dimensional Joint Inverse Model of Gravity and Magnetic data from Kilbourne Hole

The traditional geophysical inverse model was formulated for one single data set by Goltsman (1982) and Tarantola (1987). Most geophysical inverse problems have to deal with uncertain information in the observed data and *a priori* knowledge. By jointly making interpretation from two sets of data, we can limit those uncertainties. The joint inverse model uses integrated multimethod geophysical data to yield the solution of geophysical inverse problems. The traditional way of performing joint interpretation of magnetic and gravity data is based on a laboratory empirical correlation between rock density and rock magnetic susceptibility (Hrouda, 1982; Bosch and McGaughey, 2001). In order to determine the internal structure of Kilbourne Hole, a joint inversion of the magnetic and gravity survey data was done using *Geosoft Oasis Montaj-GM-SYS* software. *Oasis Montaj* provides an automated workflow for determining the position (distance and depth), dip, density, and magnetic susceptibility of geological bodies for given magnetic and gravity profiles. To obtain the result, the software implemented with three mathematical approaches: Werner deconvolution; analytic signal deconvolution; and extended Euler deconvolution (Mushayandebvu el al., 2001). To perform joint gravity and magnetic inverse model, we imported together both data components into the same conceptual model. We then build several model bodies representing geological units in the

field and assign to them initial widths, thicknesses, densities, and magnetic susceptibilities. The software algorithms iteratively calculated the shape of the model body that could yield similar anomaly to the observed anomaly. The quantitative result from the joint inversion method still however carried the uncertainty. Additional geological knowledge is required to reduce this ambiguity and to provide the uniqueness of the model solution. The additional geological information we used to constrain our model includes:

1) Topography. We used the SDTS digital elevation model with 1/3 arcsecond (~10 m/pixel) resolution (USGS, 2009) to constrain the surface topography;
2) Surface Geology. Geologic mapping of Kilbourne Hole was completed in November 2014 (Figure 3). All our field measurements (e.g., rock formation thickness, strike and dip angle) are included in our model. There are a total of 8 units included in our model (see Table 1).
3) Magnetic susceptibility. We assigned magnetic susceptibilities to each rock unit using values derived from the empirical work of other researchers (Gubbins and Herrero-Bervera, 2007; Shearer, 2005; Hunt et al., 1995; Gidley and Stuart,1980) and our own *in situ* magnetic susceptibility measurements made using a SM-30 magnetic susceptibility field meter (see Table 1.).
4) Density. The densities used in the model are based on Dorren and Seijmonspergen (2003) and Tenzer et al. (2011) (see Table 1).
5) The spatial distribution of the geological bodies. We developed a Tilt angle derivative (TDV) map of the gravity data and a TDV map of the magnetic data from Kilbourne hole. The TDV map defines the edges of the anomaly providing their estimated locations and horizontal dimensions.

4.5 Volumes and Mass Estimation

The joint inversion model provides us the spatial location of geologic bodies inside Kilbourne Hole such as pyroclastic units, crater, the diatreme and the dike. We developed a MATLAB code (Appendix C) to calculate the volume of subsurface geologic bodies and the total volume of excavation.

Our joint inversion model yields two-dimensional, cross-sectional views of the internal structure of Kilbourne Hole. The volumes of the various geologic bodies can be estimated from these cross-sectional views. To do this, the cross-sectional shapes of the bodies of interest are exported in `.csv` format from *Geosoft Oasis Montaj-GM-SYS* to MAT LAB. We then plot these data using the `scatter` command in MATLAB and use the `alphashapes` command to determine the best-fit polygons to the cross-sectional shapes. The `alphavol` command is then used to compute the area inside the polygons using Delaunay triangulation (Jonas Lundgren, 2010).

To convert the cross-sectional areas to volumes, assumptions about the geometry of the bodies need to be made. It is not certain if the geological bodies are cylindrical or cone shaped. For our purposes, we assume that all the geologic bodies are in rectangular prisms. The width of the geological bodies are derived from the magnetic TDV map where the edge of the bodies are detectable (see Figure 16). The magnetic TDV map provided better edge detection than the gravity TDV map. We speculated because the magnetic susceptibility contrast between magma and pre-eruptive units are greater than the gravity contrast between magma and pre-eruptive units. Multiplying the surface area of a body by its length yields the volume of the body as if it is in rectangular prism.

4.6 Statistical Analysis and Error Propagation

The experimental data measured and observed from our gravity and magnetic model is not perfect. We directly measure dimensions of geological bodies of interest on our developed 2D joint inverse model of Gravity and Magnetic data from Kilbourne Hole, but the measurements contain errors. The variation inherit in the errors can be from numerous factors that interfere with the measurement. Even though we made every effort to reduce systematic errors, it is impossible to totally eliminate all measurement error. For the measurements to be truly representative of the underlying phenomenon and the process we are observing (in our case, the phenomenon are e.g. the dimensions of Kilbourne Hole internal structures, the thickness of pyroclastic flow layers, the volumes of the dike, and the mass of excavation), we report the error of our result and provide confidence limits to describe the region of the true value of the variable in term of uncertainty (δ). Here we also used the measurements from our models to infer to the value of other quantities indirectly, for example, if we want to know the volume of the pyroclastic flow unit, we measured the thickness of a unit from our model cross-section and measured the surface area of the unit from our gravity anomaly map. The volume of the unit is then calculated as the thickness and the surface area multiplied. The errors in the measurements of the thickness and the surface area were translated and propagated into the achieved volume result following the Gaussian equation for normally distributed errors method (Taylor, 1997; Bevington and Robinson, 2002). Taylor (1997) and Bevington and Robinson (2002) summarized some rules for error propagation; If we have quantities a, b, c with uncertainties δa, δb, δc, the Gaussian equation for normally distributed errors are used slightly different based on the relationship and function between a, b, and c. Assuming the uncertainty are relatively small and

there is no covariance between them, then we are be able to derive the propagated uncertainty using the Gaussian equation for normally-distributed errors method.

5. Results

5.1 Gravity and Magnetic Anomaly Maps of Kilbourne Hole

The magnetic anomaly map (Figure 5a) of Kilbourne Hole reveals three magnetic anomalies associated with: (1) buried basaltic flows and dikes; (2) the Camp Rice formation and older units that pre-date the eruption, as well as reworked material that post-dates the eruption; and (3) pyroclastic deposits associated with the Kilbourne Hole eruption. The contrast in total magnetic anomaly between (1) and (2) is ~600-800 nT, whereas the contrast between (1) and (3) is ~100-300 nT. Our magnetic maps can be used to locate buried basalt lava flows, dikes, and faults that are not evident at the surface.

The gravity anomaly map (Figure 5b) of Kilbourne Hole reveals three anomalies associated with: (1) the diatreme and dikes; (2) the Camp Rice formation and older units that pre-date the eruption; and (3) buried basalt lava flows. The contrast in total gravity anomaly between (1) and (2) is ~40mGal, whereas the contrast between (1) and (3) is ~20 mGal. Unlike the magnetic anomaly map, the gravity anomaly map does not show significant detail. It is very difficult to identify and locate buried basalt lava flows, dikes, and faults that are not evident in surface exposure from the gravity anomaly map of Kilbourne Hole.

The Kilbourne Hole intrusive dikes appear on both the gravity and magnetic models. This confirms the volcanic origin of Kilbourne Hole and spatial distribution of the buried volcanic vent. Although it is not obvious on the gravity anomaly map, evidence of crater collapse is very obvious in the magnetic anomaly map (Figure 5 a and b). There are several magnetic anomaly bodies inside the crater that showed similar magnetic susceptibility to the pyroclastic deposit. We interpret that magnetic anomalies belonging to the rotated block of pyroclastic deposit can be found inside the crater.

5.2 Magnetic Tilt Derivative Map and Gravity Tilt Derivative map of Kilbourne Hole

The tilt derivative map (TDV) of the magnetic anomaly shows the edges of the dikes more precisely (Figure 6a) than the magnetic anomaly map itself. The tilt derivative map of the Bouguer gravity anomaly map of Kilbourne Hole reveals more distinctive features of mafic intrusion than the gravity map itself (Figure 6b). As seen on the TDV map of the gravity anomaly, the anomaly of the intrusions appeared to be narrower and stronger that the anomaly of the intrusions on the gravity anomaly map. Our magnetic and gravity tilt derivative maps show areas of positive tilt angle derivative (approximately 1.4 radian) and areas of negative tilt angle derivative (approximately -1.4 radians). The areas where there are no changes in tilt angle derivative (tilt angle derivative ~ 0 radain) (white ovals in Figures 6a and 6b) are considered to be the edges of intrusions (Miller and Singh, 1994). Small changes (close to 0 radians) in the vertical derivative indicate that the buried bodies must be located at great depth.

5.3 Two-Dimensional Gravity and Magnetic Joint Inversion Model of Kilbourne Hole

Figures 7-9 show the results of the gravity-magnetic joint inversion along three transects (A1-A1', A2-A2', and A3-A3') across the Kilbourne Hole (Figure 5). The RMS misfits between predicted magnetic anomalies to the observed magnetic anomaly are 64.628 nT (16.57%), 187.268 nT (5.59%), and 33.633 nT (5.69%). The RMS misfits between our predicted gravity anomaly to the observed gravity anomaly are 5.968 mGal (9.94%), 5.647 mGal (17.11%), and 5.254 mGal (15.01%). Our models reveal three dikes underneath Kilbourne Hole. The depth below the pre-eruption ground surface to the top of the dikes varies: dike 1, on the eastern rim of

the crater, is 1.75-2.25 km deep; dike 2, beneath the center of the crater, is 0.91-3.58 km deep; and dike 3, beneath the western rim of the crater, is 0.14-2.50 km deep. The depth to the bottom of the diatreme is 13.6-15.8 km and the width of the diatreme features is ~4-km wide. The models show that the tuff ring deposits extend 600 m to 1 km away from the crater rim and vary in thickness (50-150 m). On the west rim of Kilbourne Hole, the tuff ring is generally thinner, but it extends further out, compare to the tuff ring formation seen on the east rim of the crater where the pyroclastic deposits are the thickest (Figures 7). The model also suggests the presence of a series of normal faults within Kilbourne Hole that may be the result of post-eruption crater collapse (Figures 7-9).

All three inversion models of Kilbourne Hole are able to delineate several complex fault blocks of pyroclastic deposits that collapsed and rotated into crater, the area of the diatreme, the area of the original crater excavation, and the area that was later filled with alluvium. The diatreme has a cone shape with steep sides, and includes rotated blocks of pyroclastic deposits and pre-eruptive units. To confirm that all three inversion models are geologically and geometrically consistent, we visualized them with fence diagrams (Figures 10-12). The fence diagrams show the connectivity of three dikes among transects A1-A1', A2-A2', and A3-A3'. The diatreme extends down from the post-eruptive crater floor to the feeder dikes below. The thickness and the extent of the diatreme obtained from the three transects are 13.6 -15.8 km deep and is about 4 km wide.

5.4 Volumes, Mass, and Litho-Static Pressure Estimation

Figures 13-15 show the cross-sectional area and the volume estimations of the three dikes underneath Kilbourne Hole. We inspected the cross-sections along transects A1-A1', A2-A2', and A3-A3' (Figures 7-9) to determine the most representative cross-sectional areas for each dike for the purpose of calculating volumes. For example, dike 2 can be seen in both transect A1-A1'and A2-A2', and its cross-sectional area in transect A2-A2' is larger than what it is on transect A1-A1'. Therefore we choose the area of dike 2 along transect A2-A2' to best represent cross-sectional area of dike 2. The uncertainty of the cross-sectional area is propagated from the uncertainty of the width of the body in y direction and the uncertainty of the depth the body in z direction. We made an assumption that the dikes are elongate along the fault and are in rectangular prism. We measured the diameter of the dikes and other volcanic structure of Kilbourne Hole on TDV magnetic map of Kilbourne Hole (Figure 16). The length of dike 1 is ~0.98 ± 0.1 km. The uncertainty is based on the spatial resolution of our magnetic anomaly map and magnetic TDV map. The map was interpolated from our 200 m resolution data. Therefore the certainty of model result should only be half the resolution, which is 100 m or ±0.1 km. Similarly, the length of dike 2 is ~0.55 ± 0.1 km, and length of dike 3 is ~0.51 ± 0.1 km. By multiplying the cross-sectional area of each intrusion by its length, we obtained the volumes of dike1, dike2, and dike 3: 1.98 ± 0.29 km^3, 1.47 ± 0.29 km^3, 1.02 ± 0.23 km^3, respectively. The uncertainties of the cross-sectional area are propagated from the uncertainty of the diameter of the cross-sectional area, which is ±0.1 km, and the uncertainty of the depth or the thickness of the cross-sectional area, which is ~ ±0.12 km. This uncertainty is based on the sensitivity our model. By trial-and-error, we found that the thickness and the depth of the buried dikes can be varied up to ±0.12 km and still yield an acceptable model misfit. By combining the total volume

of the dikes, including their uncertainties, we estimate that the total volume of the basaltic magma that caused the Kilbourne Hole eruption was 4.46 ± 0.0.48 km^3. Using the density of basalt (3100 kg/m^3), we estimate the total mass of the melt (m_m) to be (1.38 ± 0.15) x 10^{13} kg. Similarly, we calculate the total volume of the volcanic fragments excavated during the Kilbourne Hole eruption to be 1.55 ± 0.23 km^3 and the total mass that was excavated to be (2.53 ± 0.38) x 10^{12} kg. The total volume of the Kilbourne Hole diatreme was 14.2 ± 0.17 km^3 (we do not need to know the mass of the diatreme to solve for equation (8), so we left with the mass of the diatreme uncalculated). All calculations, including error propagation, are shown in detail in Appendix D. Errors from all measurements were propagated when the measurements are used to obtain other indirect results using the procedure provided by Taylor (1997) (see section 4.6).

Because all three sections of our integrated gravity and magnetic models of Kilbourne Hole reveal intrusions at depths between 0.14 km and 3.5 km, we assume that the depth of 3.5km is where the maximum pressure from litho-static load occurred. The Kilbourne Hole vent material from the surface to the depth of 3.5 km includes: (1) ~3.47 km thick diatreme filled material with a density of ~2,560 kg/m^3; and (2) 0.03 km of basalt with a density of ~3,100 kg/m^3. Therefore the thickness-weighted density of the Kilbourne Hole litho-static load is 2,507 kg/m^3. Using Equation (6) we calculated that the litho-static load pressure (p_1) inside the vent of the Kilbourne Hole was 8.81 x 10^2 bar.

5.5 Mass of Water in the Groundwater Reservoir

We calculated the mass of groundwater in the groundwater reservoir at the time of eruption by substituting these following variables into Equation (8):

1) A maximum ejection velocity of 122.8 ± 9.3 m/s (113.5-132.2 m/s; Rhodes and Hurtado, 2014),
2) The total volume of the diatreme, 14.2 ± 0.17 km^3 (we do not need to know the mass of the diatreme to solve for equation (8), so we left the mass of the diatreme uncalculated).
3) The total volume of the excavated volcanic fragments, 1.55 ± 0.23 km^3
4) The total mass that was excavated, ~ (2.53 ± 0.38) x 10^{12} kg.
5) The total mass of all three dike (section 5.4), ~ (1.46 ± 0.33) x 10^{13} kg

From the calculation of equation (8), we calculated the mass of water (m_w) involving in Kilbourne Hole eruption to be (1.09 ± 0.31) x 10^{13} kg. The ratio of mass of water to mass of magma and the known mass of the magma (m_w/m_m) is 0.79 ± 0.23 (Figure 17).

6. Discussion

6.1 Geologic interpretation of Gravity-Magnetic Joint Inversion Model of Kilbourne Hole

Unlike most regional gravity and magnetic models of a typical volcano, our gravity and magnetic survey of a phreatomagmatic volcano such as what we did at Kilbourne Hole provided ~ 200 m resolution gravity and magnetic anomaly map. The 2D joint gravity-magnetic inversion from our ~ 200 m resolution gravity and magnetic anomaly map allowed us to model the internal structure of Kilbourne Hole in great detail. The geometrical results of our joint gravity and magnetic model of Kilbourne Hole shows great similarity between the internal structure of Kilbourne Hole and the internal structure of other phreatomagmatic volcano described by White and Ross (2011). Both our model of Kilbourne Hole and White and Ross (2011) models of phreatomagmatic volcano are consistent with a zone of chaotic breccia that is cut by multiple dikes at various depths (Figure 10-12). Beyond that, our model of Kilbourne Hole revealed the structure of rotated blocks of pre-eruptive units, and rotated blocks of collapsed crater rim material. However. Our models are also able to show the transition from the diatreme to the intrusion in the root zone of the phreatomagmatic volcano and the spatial distribution of the buried rotated blocks and the post –eruptive crater filled material (Figure 10-12). The depths of the diatreme roots (at ~ 13.6-15.8 km) and the depth of the basement rocks (~1.5 – 4.6 km) in the vicinity beneath Kilbourne Hole crater provided on all 3 cross-sectional models are correlated to other workers estimation of the Potrillo Volcanic Field (PVF) and the Mesilla basin. Averill (2007) and Gillespie (2002) suggested the basement rock of both western and eastern flank of the Mesilla basin are at the shallower depth than the rest of the Rio Grande basin. Their seismic and regional gravity models suggested the Mesilla basin is an asymmetric basin adjoining on the eastern side to the PVF and on the western side to the base of the Franklin mountain uplifts.

Averill (2007)'s seismic velocity models indicate that the Mesilla basin upper crustal basement rock is ~3-5 km deep and is defined by velocities of 5.96-6.09 km/s. The seismic velocity profile of the PVF also shows a distinctive thickening layer of mid-crust with a velocity contrast of 6.2 - 6.35 km/s at depths of 11-12 km. This distinctive layer is not the layer of the lower crust with velocity of 6.15-6.62 km/s at ~20 km, neither upper mantle with velocities of ~7.8 km/s at 30-31 km depth (Averill, 2007). Previously Averill (2007) was not certain of his interpretation of this thickening mid crust at the depth of ~11-12 km. It was noted that this middle-crust's interface is located abruptly at approximately 20 to 12 km depth just to the west of the PVF. This interface also shows a crustal thickening trend beneath the PVF. The velocities range from 6.28 to 6.4 km/s and the densities range from 2.75-2.88 g/cm^3 of these mid-crust is not high enough to be interpreted as the magma chamber or lower curst and is not low enough to be interpreted as the limestone type upper crustal basement rock. Averill (2007) interpret this mid-crust anomaly may be an extensional faulting that may relate to volcanism in the PVF region. Our gravity and magnetic models of Kilbourne Hole was performed with 200 m spacing in the PVF region and contain sufficient detail to resolve this feature. Our interpretation of the geological bodies at the depth of 13.6-15.8 km with the density of 2.58-2.64 g/cm^3 is that this feature is a diatreme of Kilbourne Hole, is supported by the previous interpretation of Averill (2007).

A minimum of three dikes were found at various depths inside Kilbourne Hole. Each dike may be a record of changes in the location of individual explosions during the eruption. Because in a phreatomagmatic eruption, the dike that came to interact to groundwater sources tend to lose its heat and became frozen dike buried at the location where its last interact with groundwater. Another observation made based on our model of Kilbourne Hole are that the spatial location of

the dike not at the center of Kilbourne Hole. The spatial distribution of the dikes may also be an explanation of the irregular shape of Kilbourne Hole (see Figures 10-12).

Our inverse models of Kilbourne Hole indicate that the magnetic signal is more sensitive to the geometry of the subsurface bodies at Kilbourne Hole than the gravity signal. This may be because the magnetic susceptibility contrast between the mafic intrusions underneath Kilbourne Hole and the Camp Rice formation is very high, so that even slight adjustment could result in great change in magnetic anomaly.

With the vertical tilt derivative method applied to the magnetic data, we are able to better locate the edge of the dikes and the diatreme. The dike when buried deep inside the diatreme, instead of providing a sharp narrow anomaly on the map, it only shows broad and wide anomaly on the map with no distinction to the anomaly of the surrounded alluvium. Without the help of tilt derivative method, we may not be able to model the edge of the dikes.

6.2 Paleohydrological Conditions of Kilbourne Hole at the Time of Eruption

With reliable constraints for the internal structure of Kilboune Hole, we estimate that the groundwater reservoir at the time of the eruption supplied $(1.09 \pm 0.31) \times 10^{13}$ kg of water. The volume of this amount of groundwater was approximately 10.87 ± 3.12 km^3. To provide a perspective to how much water was in the groundwater reservoir, we made an assumption that Kilbourne Hole's aquifer has an approximate volume of ~ 64 km^3 (4 x 4 x 4 km), considering that the Mesilla basin were filled with ~4km thick sediment and the size of Kilbourne Hole was about 4 x4 km. This volume of groundwater in comparison to the volume of Kilbourne Hole's reservoir suggested that it is ~16.9 ± 4.8% of groundwater. The water to magma mass ratio,

therefore, was 0.79 ± 0.23. Wohletz (1986), Wohletz and Sheridan (1982; 1983), and Wohletz and McQueen (1984) suggested (Figure 17) that the Kilbourne Hole's phreatomagmatic eruption produces thinly-bedded, dry base surge, and vapor-expanded tuff ring. Our results are supported by the observation of thinly bedded dry base surge, and extended tuff ring deposit along the rim of Kilbourne Hole (Figure 18). The evidence of boulder sized volcanic blocks and associated sags also confirm that the eruption event that formed Kilbourne Hole was highly explosive.

This percent of groundwater is also supported by the paleohydrologic conditions in the Mesilla basin during the Plio-Pleistocene. With ~16.9 ± 4.8% of groundwater, the climate condition of the Mesilla basin may have been wetter than the present day Chihuahua desert climate (Mack et al., 2014). For example, Mack et al. (2014) observed carbon isotopes of pedogenic carbonates from the Camp Rice formation and suggested that the climate of the lower Rio Grande basin in Late Pleistocene time showed a steady trend toward higher temperatures than today's and summer-dominated rainfall. Kilbourne Hole is located on the southwestern edge of the Rio Grande basin; therefore, it should have experienced the same climate trends as the rest of the Rio Grande basin. The Santa Fe group (including Camp Rice and Fort Stockton formation) is the main aquifer of all groundwater sources within the Rio Grande basin. Today it is estimated that the Santa Fe group aquifer is about 1-5 km thick (Keller et al., 1990) and the depth the groundwater level is 1.5-4.8 km (Robson and Banta, 1995). Our model suggests that the mafic intrusions that triggered the Kilbourne Hole explosion interacted with groundwater at about 0.17-3.58 km depth. This suggests that the groundwater level in the Rio Grande basin at the time of Kilbourne Hole eruption was higher than it is today.

6.3 The application of gravity and magnetic surveys on Mars Home Plate

Our gravity and magnetic survey at Kilbourne Hole had demonstrated that we could quantify the amount of groundwater involving in a phreatomagmatic eruption using the result of our 2D-gravitya and magnetic joint inversion model results. The gravity and magnetic surveys we did at Kilbourne Hole can be used as a guideline to design similar surveys of phreatomagmatic craters and other volcanic activities on a planet such as Mars or the Moon to understand their paleo-hydrological conditions. Because the geological and geophysical setting of Kilbourne Hole is very similar to what we observe at Home Plate on Mars (e.g., cross-bedded pyroclastic flow deposit, basalt flow deposit, volcanic blocks and sags features, size of volcanic blocks and thicknesses of their ash bed) (Figure 18), it is possible that internal structures similar to Kilboune Hole could also be well preserved underneath Mars Home Plate. Even with the highest resolution of the most recent GRAIL and MGS (Mars Global Surveyor) gravity data from the Moon and Mars, its resolution of ~7.6 km is still not sufficient to detect an anomaly from a volcano the scale to Kilbourne Hole eruption, we suggested a high resolution ground-based gravity and magnetic data are needed on Mars and the Moon. All of ground based gravity and magnetic survey may be completed by a rover but it may also require the geophysicist to provide a survey that it was carried out accurately, and to interpret the results using *a priori* geological information. To do a gravity and magnetic survey on Mars, there are several factors to consider:

1) Rocks formed after the core dynamo ceased may yield an opposite anomaly of the same geological feature as on Earth (Cisowskil and Fuller, 1978; Isac et al., 2015);

2) Magnetic susceptibilities many not have been the only attribute to remnant magnetization and magnetic signal anomalies. Large impacts can de-magnetize or re-magnetize rocks and altered rock density; and
3) To date, there has been little work to systematically determine the magnetic susceptibility of rock types on Mars (Cisowskil and Fuller, 1978; Isac et al., 2015).

A ground-based magnetic and gravity survey using 200 m spacing similar to what we did at Kilbourne Hole should be sufficient to map the volcanic activity on Mars Home Plate. However, the traditional data processing and interpretation on the magnetic data retrieved from Earth is not completely adaptable on Mars. Firstly, because any volcanic rock that formed after the core dynamo on Mars ceased (Isac et al., 2015; Langlais et al., 2010) would not yield any magnetic anomaly and therefor is not appropriate for modeling method (Cisowskil and Fuller, 1978; Isac et al., 2015). Secondly, de-magnetized or re-magnetized rocks due to large impact event would complicate magnetic data correction. On Earth, our dipole magnetic field are in N-S direction and we can perform reduce to pole correction so that all the anomalies are aligned in the same direction prior the model inversion. On Mars remanents magnetic field are not in N-S direction but in fact are depend on the zone of de-magnetize or re-magnetize. Without a detail map of Mars remanents magnetic field, the surveyor would not be able to perform sufficient magnetic data correction to achieve a reliable magnetic model. Lastly, because there are no rock samples from Mars; the information about Mars' rocks is very limited. Only some magnetic information obtained from ALH84001 Martian meteorites can provide us constrain for magnetic modeling on Mars surfaces (Weiss et al., 2002).

To do a ground-based gravity survey on Mars is slightly less complicated than to do a magnetic survey because, both Mars and Earth are terrestrial planets of almost similar size and gravitational acceleration. The only concern in bringing ground-based gravity surveys to Mars is similar to the concern with using GRAIL data from the Moon. Both Mars and the Moon are highly bombarded by large impact events thought-out is formation history and the gravity signal retrieved from Mars surface is not a reflection of its internal structure but instead a reflection of its impacted subsurface. Similar to the Moon, the large impact events on Mars also created an abnormally high positive gravity anomaly zone called mascon (Zuber et al., 2013; Isac et al., 2015; Langlais et al., 2010). To quantitatively interpret the gravity data from Mars, we might need to consider filtering out the gravity signal from the highly impacted Mars subsurface. However, quantitatively interpreting the magnetic data from Mars is not quite possible yet for the reasons stated earlier.

Our gravity and magnetic study at Kilbourne Hole is only a pilot study on a phreatomagmatic volcano on Earth. Our result successfully yields quantitative interpretation of the internal structure of Kilbourne Hole and quantitatively estimation of the amount of groundwater involved in Kilbourne Hole eruption. In this study, we present a conceptual methodology for modeling gravity and magnetic data and solution to evaluate and to quantify the amount of groundwater (see section 4) on a terrestrial phreatomagmatic volcano site on Earth. Here we reported the strategies and the adaptation of our gravity and magnetic survey's design, gravity and magnetic data collection, and gravity and magnetic data correction on the analog site on Earth. However to carry out our study on Mars, we must first obtain more information about the physical

rock properties, particularly magnetic susceptibility and bulk density, before we can provide an adaptation of our method to be used on Mars.

7. Conclusions

In conclusion, we are able to design ground-based surveys using gravity and magnetic methods at an Earth analog site (Kilbourne Hole, NM). We concluded that our designed geophysical method could also be performed on a phreatomagmatic or volcanic outcrop on Mars and the Moon. We are also able to provide gravity and magnetic interpretation methods that do not rely solely on just the modeling method. By integrating the results of my joint gravity and magnetic model and the GPR surveys of Kilbourne Hole, we are able to provide quantitative results of the paleo-hydrogeological conditions at the time of eruption, which are mass and volume of the Kilbourne Hole groundwater reservoir. Our models allow us to interpret the internal structure of Kilbourne Hole within the geological context of the Rio Grande rift basin and the Mesilla basin. The application of the tilt derivative method also allows us to constrain the model and to retrieve precise edges and locations of the buried geological bodies. We found that the magnetic method responds very well to the bodies of high iron content basaltic intrusions as opposed to the gravity method, which cannot distinguish between the diatreme and the intrusions because they have the same density. However, our combined use of gravity and magnetic data is very helpful in: (1) delineating subsurface volcanic and sedimentary materials and (2) identifying mafic intrusions and diatreme.

The results from my study at Kilbourne Hole not only confirm the ability of our method in planetary exploration, but it also reveals important information about the internal structure of Kilbourne Hole itself. From our study, we are able to understand Kilbourne Hole's eruption history and the paleo-hydrologic conditions of the Rio Grande rift basin in much more detail than any surface geological study. Kilbourne Hole eruption was active during the Plio-Plesitocence time; where the climate amplitude and magnitude were fluctuating highly. Our quantitative result

of groundwater conditions at Kilbourne Hole aligns with the regional paleo-climate trend at the time. The ~16.9 ± 4.8% of groundwater in the reservoir shows that water activity was very high during the time Kilbourne Hole last erupted, even though the present environment is semi-arid.

The adaptation of our method on Mars is likely possible. The current climate of Mars is arid with some evidence of water presence. The modern observable cryosphere contains an equivalent global layer of water ~35 m thick (Michalski et al., 2013). It is also suggested by Burt et al. (2003) that the largest fraction of Martian water is in the subsurface in the form of briny groundwater. Mars groundwater contains greater subsurface porosity than Earth (Burt et al., 2003). It is believed that after Mars tectonic activity stopped in Noachian, Martian groundwater was no longer altered by volcanic outgas process and ultimately had become sequestered into the subsurface, and/or froze into the cryosphere, and/or lost to space (Michalski et al., 2013). Our method was specifically designed to not only provided information about the phreatomagmatic volcano's preserved internal structure but also was intent to reveal the condition of the groundwater reservoir at the time of eruption. Conducting integrated geophysical survey procedures similar to those that we performed at Kilbourne Hole on Mars would reveal further understanding to early Mars climate conditions.

However, it must be noted that our results from the gravity and magnetic surveys are not a stand-alone result. To obtain the final product of this research, which is the amount of groundwater in the reservoir at the time of Kilbourne Hole eruption, we must know the initial velocity of the gas expansion at the time of eruption which can only be retrieved from our GPR results (Chapter 3). The reliability and detail provided by our two dimensional joint gravity and magnetic model are very much dependant on the quality of *a priori* information. In other words, the more limited background geological knowledge exist of the planet, the less reliable our

model results. Therefor to practically adapt our method for Martian ground based surveys, numbers of other key observations must also be made. For example, we were unable to perform gravity and magnetic inversion modeling unless we first know what densities and magnetic susceptibility of the rock units on Mars are. In addition to present exploration of Mars that is focused on evaluating the habitability of surface environments, we argue that we may also need to look back further in time as the Martian surface had become extremely cold, oxidizing and arid long before. With further observations, great information can be learned about the climate history of the terrestrial planets through this type of research.

Table 1. Rock unit descriptions and physical properties

Rock units description and legend	Magnetic Susceptibility (10^{-3} SI)		Density (g/cm^3)	
	*ref	model	*ref	model
Post eruption deposit (Quaternary) Young alluvium, reworked pyroclastic deposits	0-20.9 [a, c]	26	1.69-2.58 [a, d]	2.174
Pyroclastic deposit of Kilbourne Hole (Quaternary) Ash flow tuffs, tuff ring, air fall (tephra)	0.65 -37.8 [a, b]	-7 to -16	1.13-2.35 [a, d]	2.2-2.3
Diatreme filling of Kilbourne Hole (Quaternary) body of brecciated rock formed by explosive or hydro-static forces, whether or not it is related to volcanism.	? ?	13-18	1.78-3.06 [a, d]	2.58-2.64
Potrillo volcanic field (Mid-Miocene - Quaternary) Basalt, basaltic andesites, andesites, and silicic tuffs	2-175 [a, b, c]	48 -147	1.54-3.00 [d]	2.820-2.996
Clastic -Camp Rice Fm. and Fort Stockton Fm. (Middle -Tertiary -Quaternary) Boulder, conglomerate, breccia, sandstone, alluvium	0-20.9 [a, c]	26-30	1.69-2.58 [a, d]	2.16
Volcanic intrusion (Middle -Tertiary - Quaternary) Diabase with peridotite xenoliths	0.2-175 [a, b, c]	174.99	2.34-3.34 [a, d]	3.28
Laramide fault-block uplift (Cambrian to Permian). marine limestone, dolomite, shale, and sandstone.	-10 - 30 [a, b,]	-2.5 to 24	1.89-3.01 [a, d]	2.07-2.16
Basement rock (Pre Cambrain) Granite	0-50 [a, b]	74.97	2.30-2.94 [a, d]	2.67

***** *Note :* These numbers are the maximum and minimum values of similar rock types reported by [a] Hunt et al. (1995), [b] Gidley and Stuart (1980), [c] Gubbins and Herrero-Bervera (2007), [d] Tenzer et al. (2011)

Table 2. List of physical parameters.

Variables	Units	Descriptions
CR	-	The conversion rate or the efficiency of the eruption
ΔKE	J	Kinetic energy of the eruption
ΔPE_{dia}	J	Potential energy inside the diatreme during the eruption
ΔPE_{sys}	J	Potential energy of the masses that were released by the eruption
ΔPE_{exc}	J	Potential energy of the masses that were excavated by the eruption
dia	-	Value for surrounding of volcanic vent structure and the atmosphere
exc	-	Value for excavated masses of magmatic particles and water vapor
p_1	bar	Litho-static load pressure in the magma source region
p_o	bar	Atmospheric pressure at the surface of the volcano
λ	-	Pore pressure as a fraction of lithostatic load
τ_o	bar	Cohesive strength of rock or other material
m_f	kg	Mass of volcanic fragments including melt and pyroclastic deposit
m_w	kg	Mass of meteoric water in a phreatomagmatic eruption
m_m	kg	Mass of magma or melt in a phreatomagmatic eruption
m_w / m_m	-	Water to magma mass ratio
v_{max}	m/s	Initial gas expansion velocity
C_{vm}	$J.kg^{-1}.K^{-1}$	Heat capacity of molten basalt
p_o	MPa	Gas pressure at the final stage of the eruption
p_1	MPa	Gas pressure at the time of eruption
V_{dia}	m^3	Volume of the entire volcanic system (the diatreme)
V_{exc}	m^3	Volume of the material excavated form the eruption
T_m	K	Temparature of molten basaltic magma
T_e	K	Temperature of an idealized Earth surface
ΔW_{sys}	J	Works in a volcanic system that causes the masses to release
ΔU	J	Magma thermal energy
θ	radian	The tilt angle derivative in vertical direction
$\partial M/\partial x$	m	The first order derivatives of the magnetic field M in the x direction
$\partial M/\partial y$	m	The first order derivatives of the magnetic field M in the y direction
$\partial M/\partial z$	m	The first order derivatives of the magnetic field M in the z direction

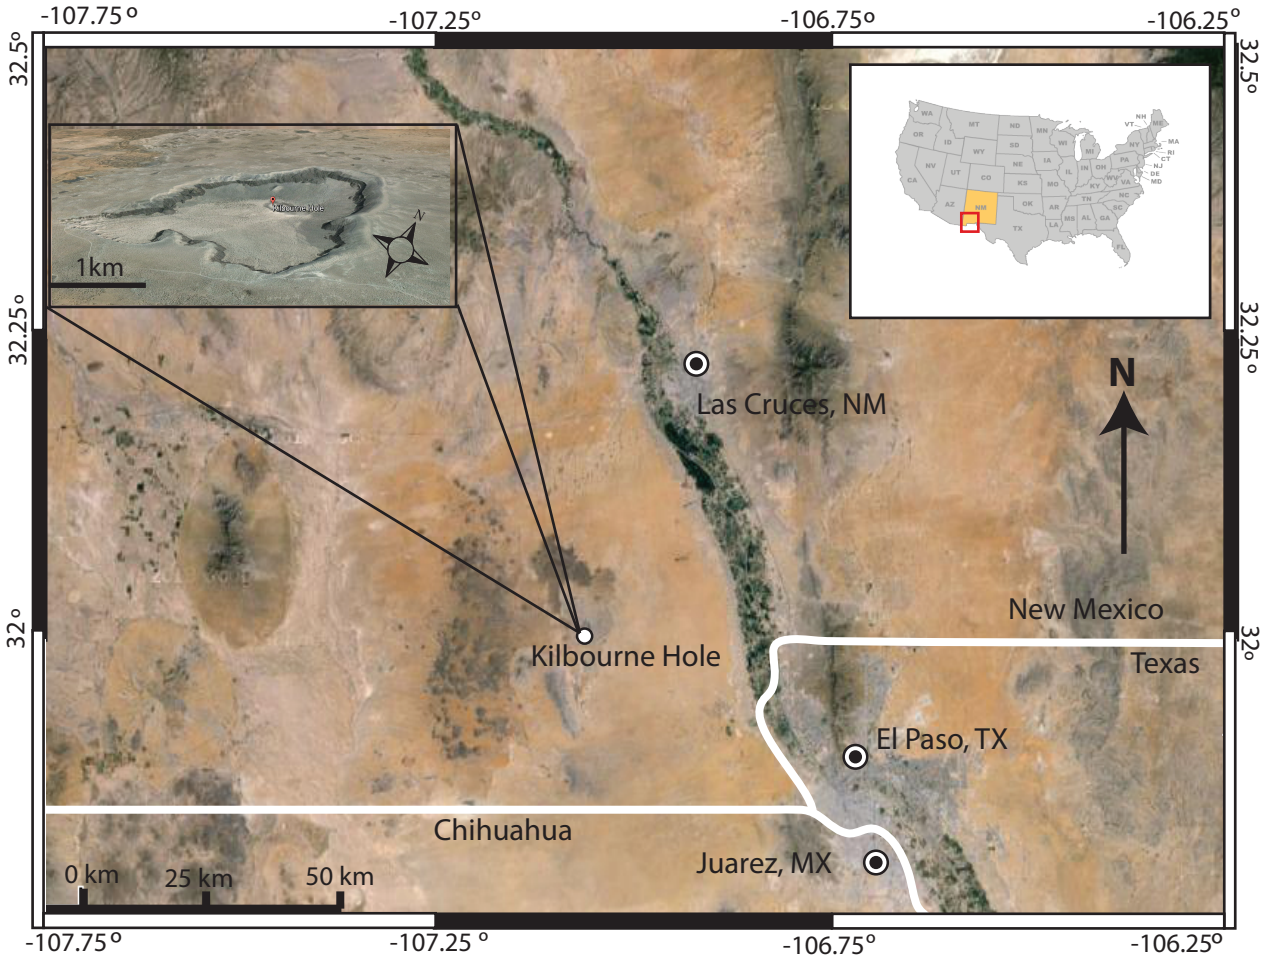

Figure 1. Location of Kilbourne Hole in southern Doña Ana County, New Mexico (imagery from Google Earth, 2008).

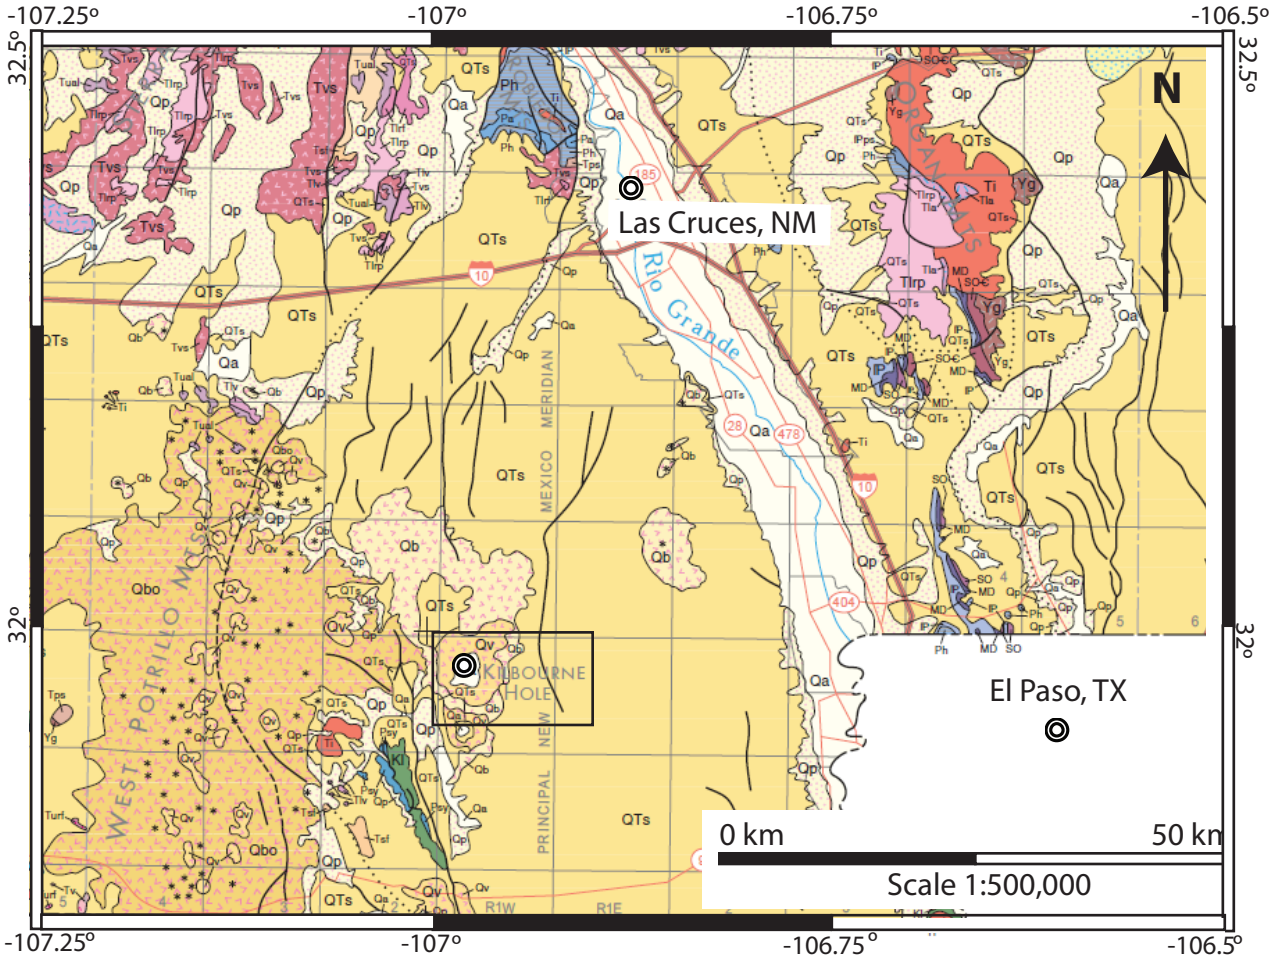

Figure 2. Geologic map of the Mesilla Basin. The Mesilla basin is the southern end of the Rio Grande basin. The box shows the location of Kilbourne Hole. Modified from Scholle (2003).

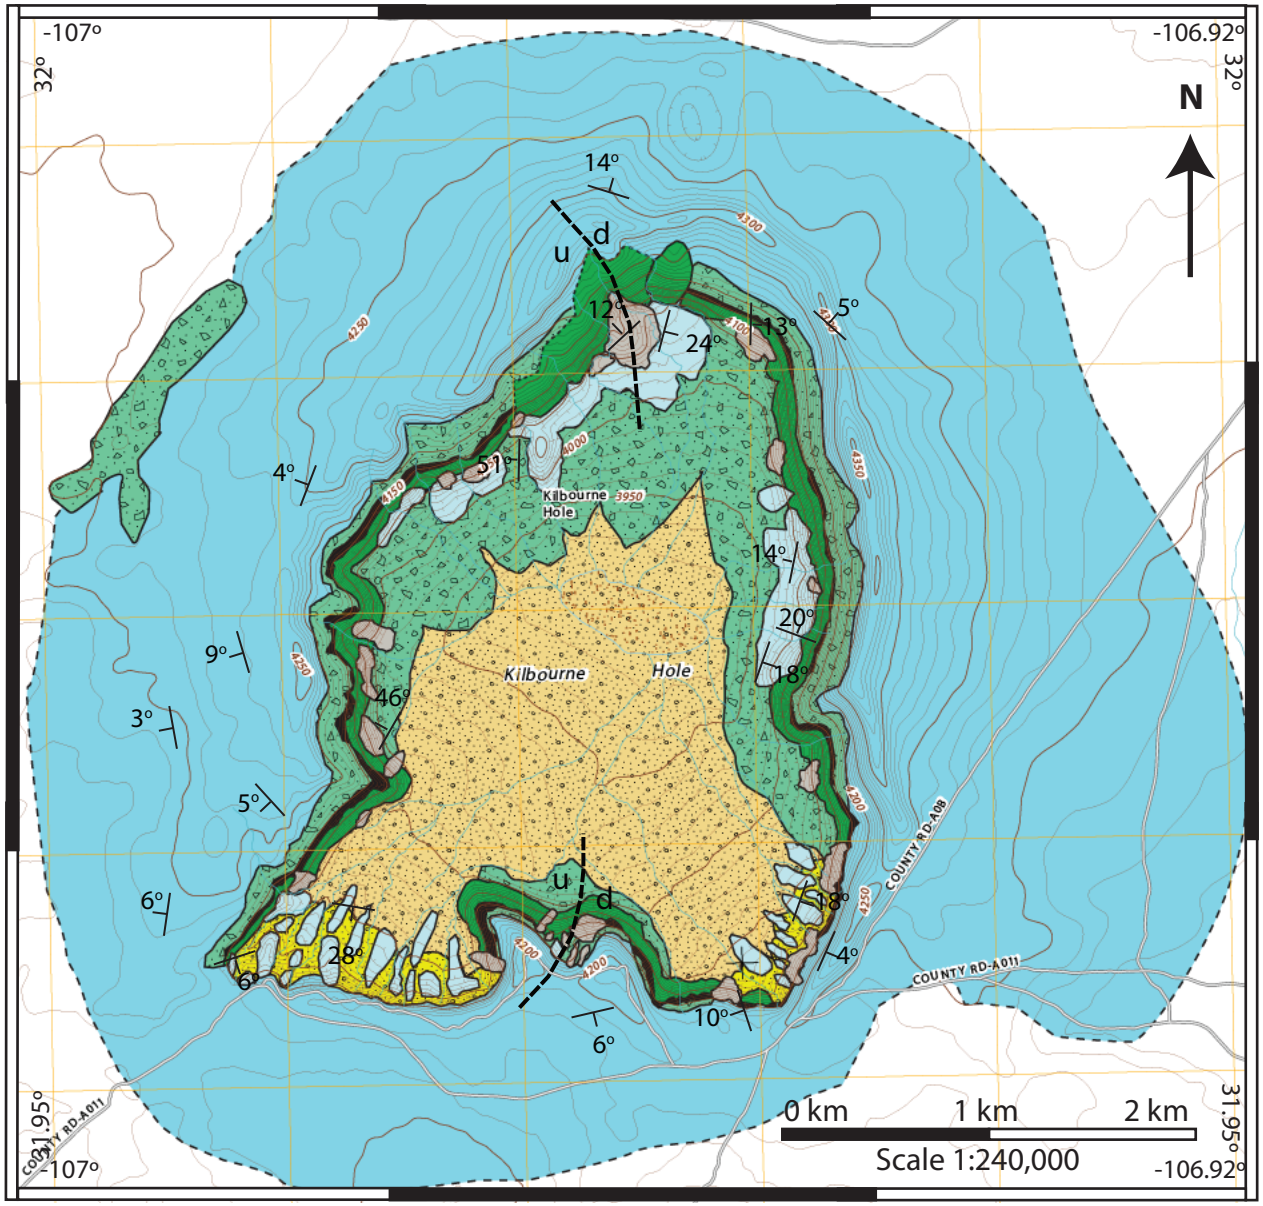

Legend

- Young Alluvium
- Talus
- Tuff Ring
- Volcanic Breccia
- Potrillo Basalt
- Camp Rice Fm.
- Contact
- Fault (u / d)
- Strike and Dip
- Rotated Blocks of Tuff Ring
- Rotated Blocks of Potrillo Basalt

Figure 3. Geologic Map of Kilbourne Hole, NM. Base map is U.S Geological Survey Kilbourne Hole Quadrangle 1:24,000 scale topographic map (USGS, 2010).

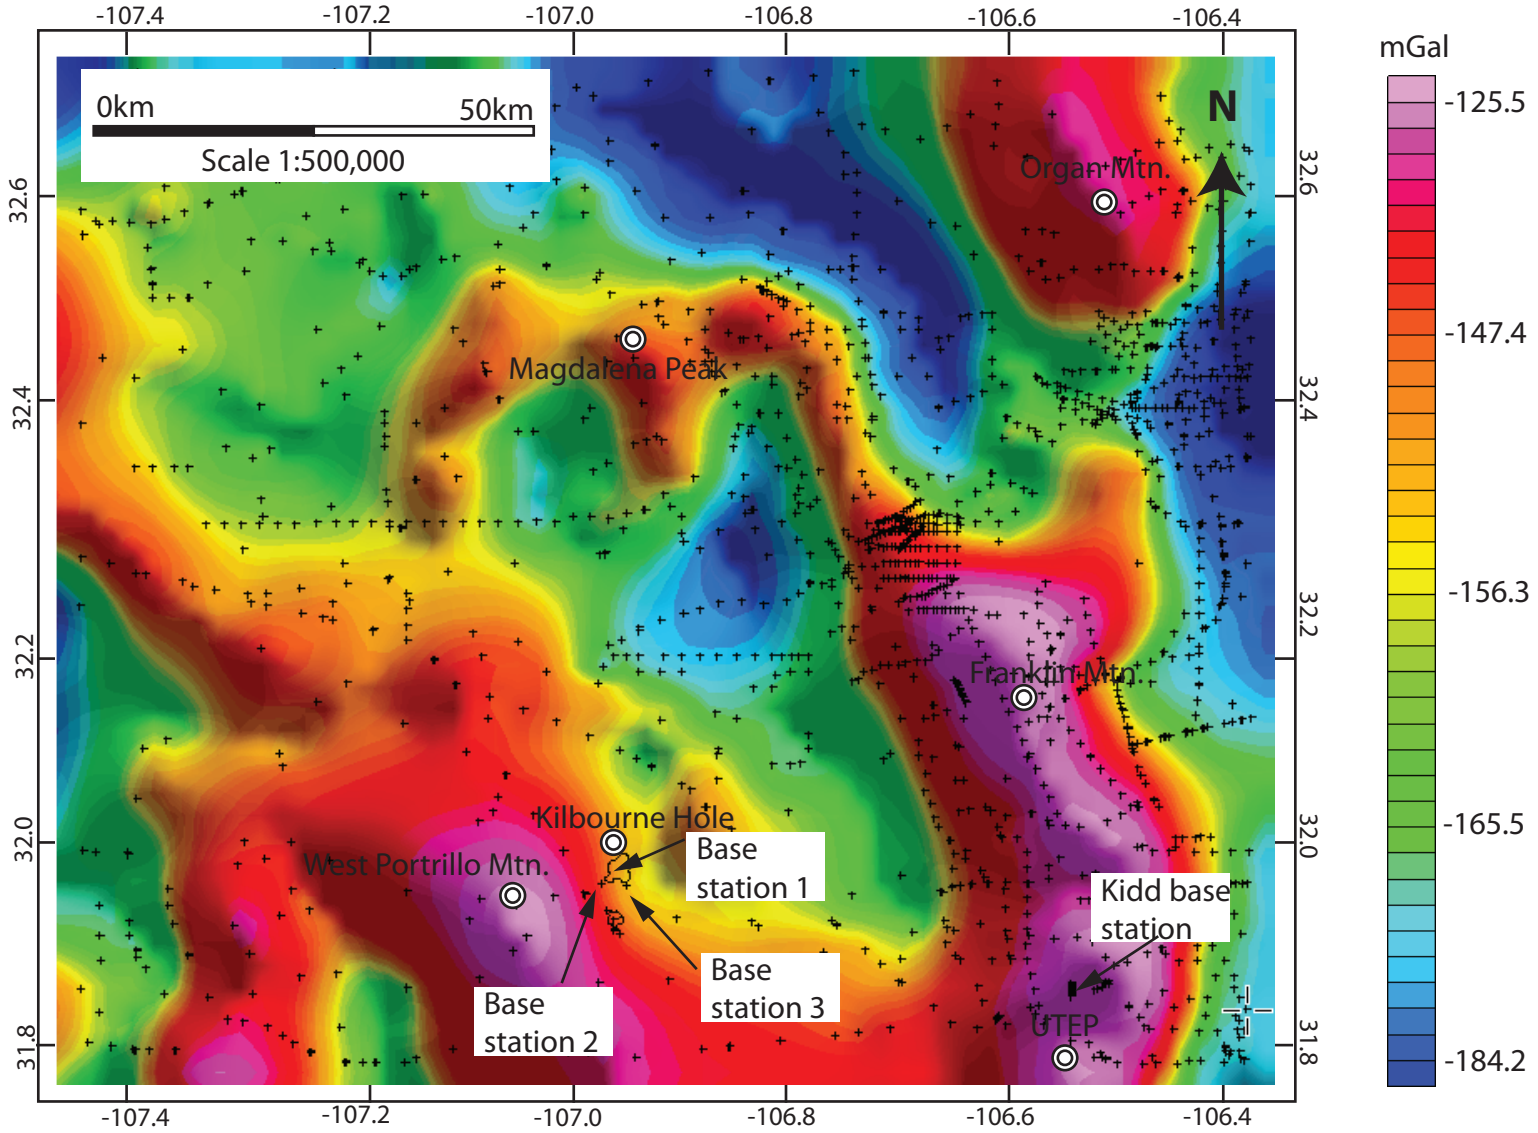

Figure 4. Bouguer gravity anomaly map of the Mesilla basin. Locations of base stations used during the gravity survey are shown. Reducing density of 2670 kg/m^3 is used for Bouguer correction. We generated this map using a set of gravity data obtained from the North American Gravity Database (Hildenbrand et al., 2002a). Black crosses are gravity stations.

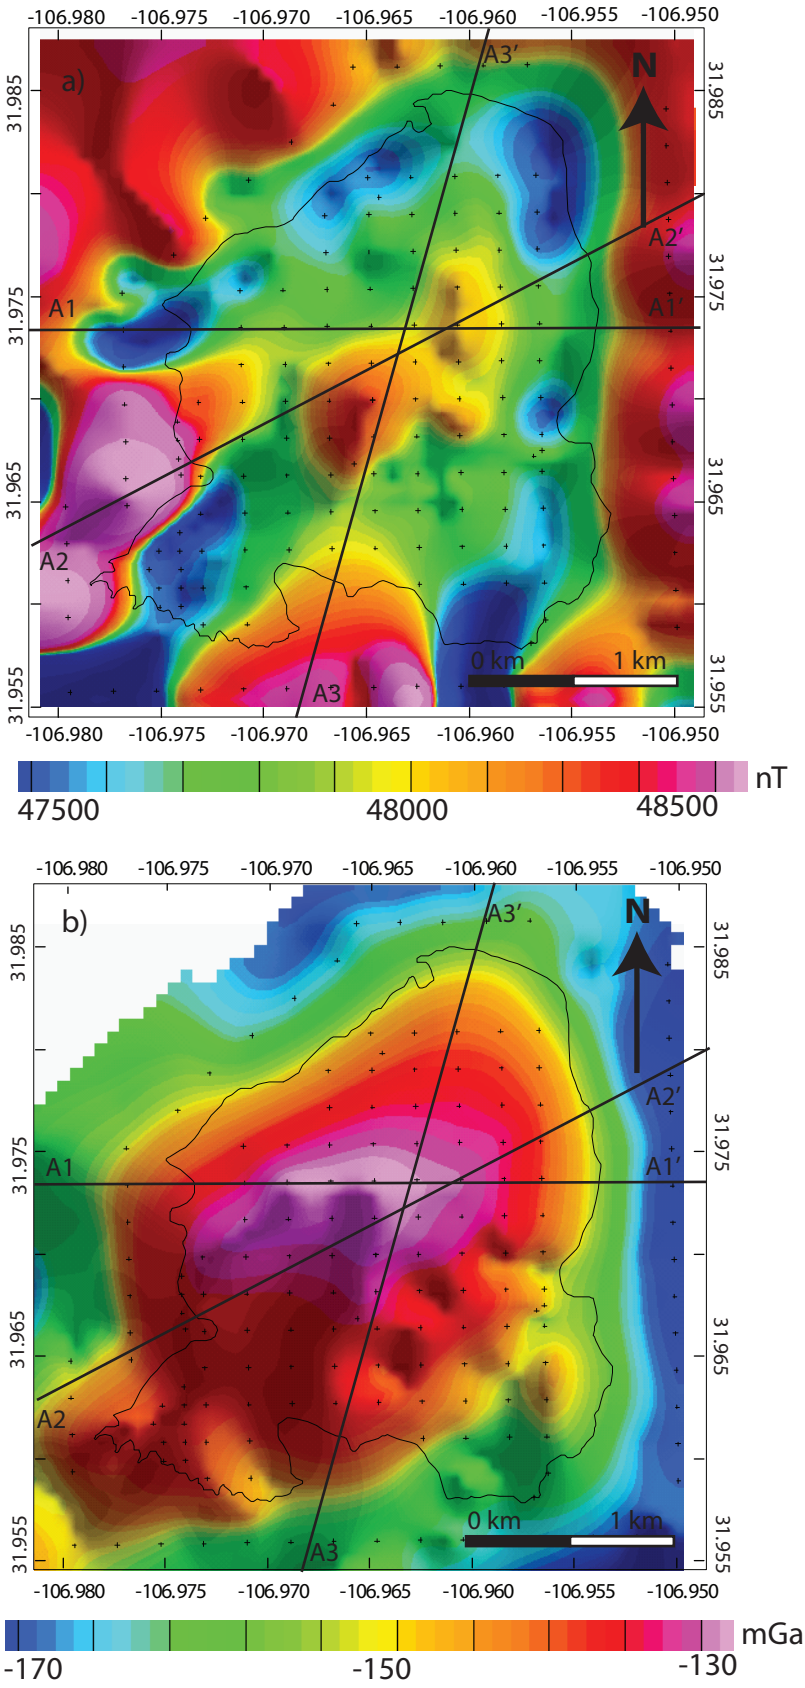

Figure 5. (a) Reduced to pole magnetic anomaly map of Kilbourne Hole (our data). (b) Bouguer gravity anomaly map of Kilbourne Hole (our data). Black lines represent the transects along which the inversion models in Figures 7-9 were constructed.

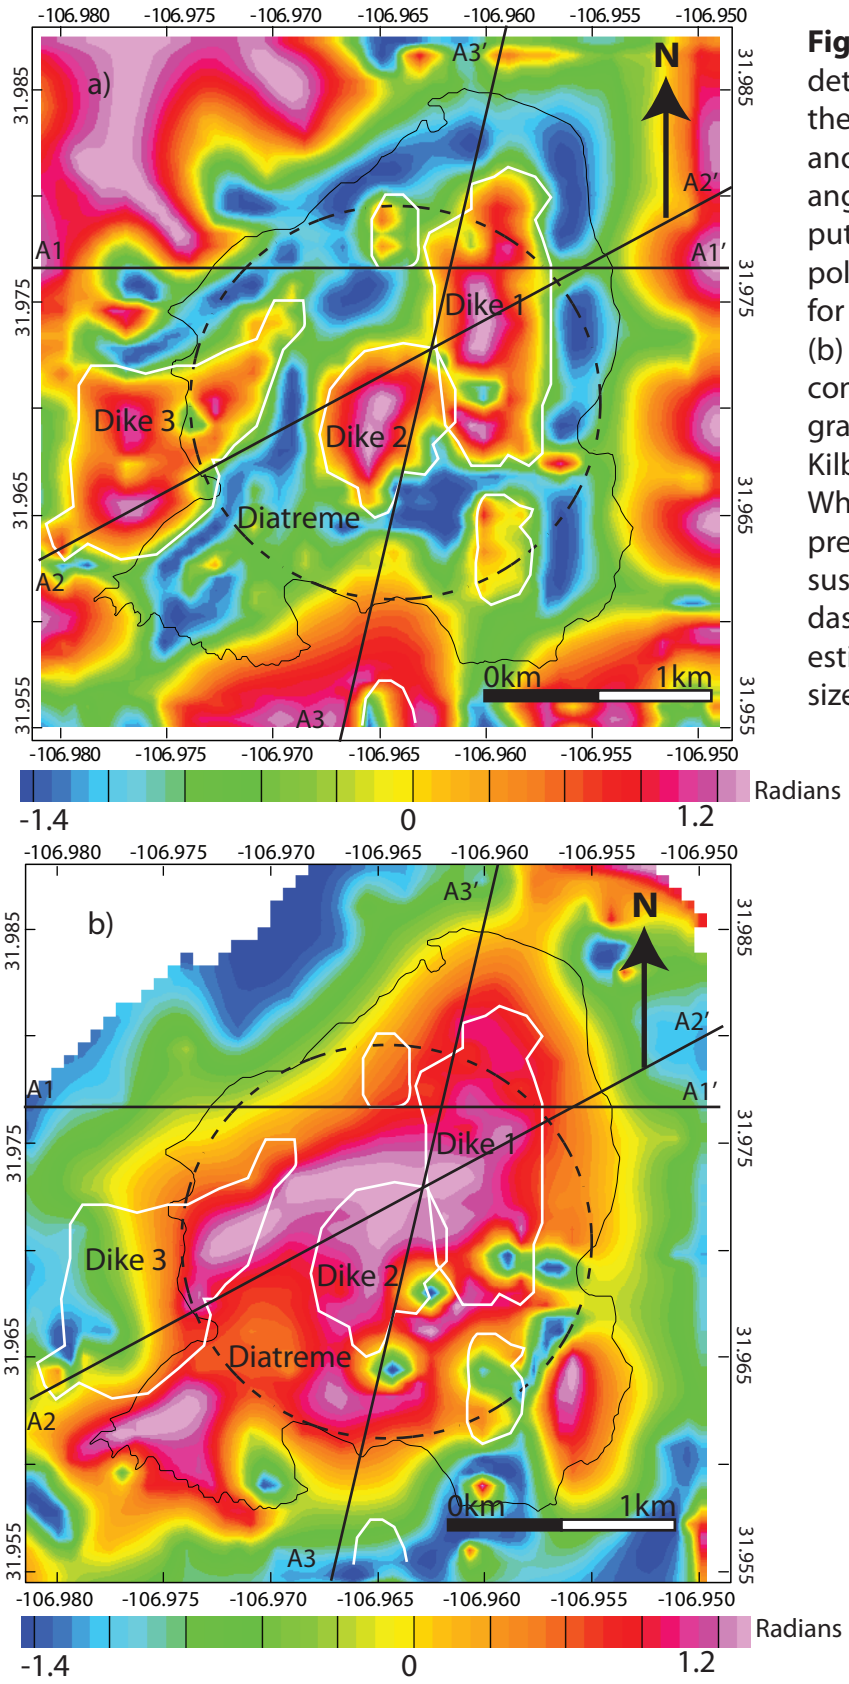

Figure 6. Results of edge detection methods applied to the magnetic and gravity anomalies in Figure 5. (a) Tilt angle derivative map computed from the reduced-to-pole magnetic anomaly data for Kilbourne Hole (our data). (b) Tilt angle derivative map computed from the Bouguer gravity anomaly data for Kilbourne Hole (our data). White outlines show the interpreted boundaries of suspected intrusions. The dashed circle denotes the best estimate for the original crater size.

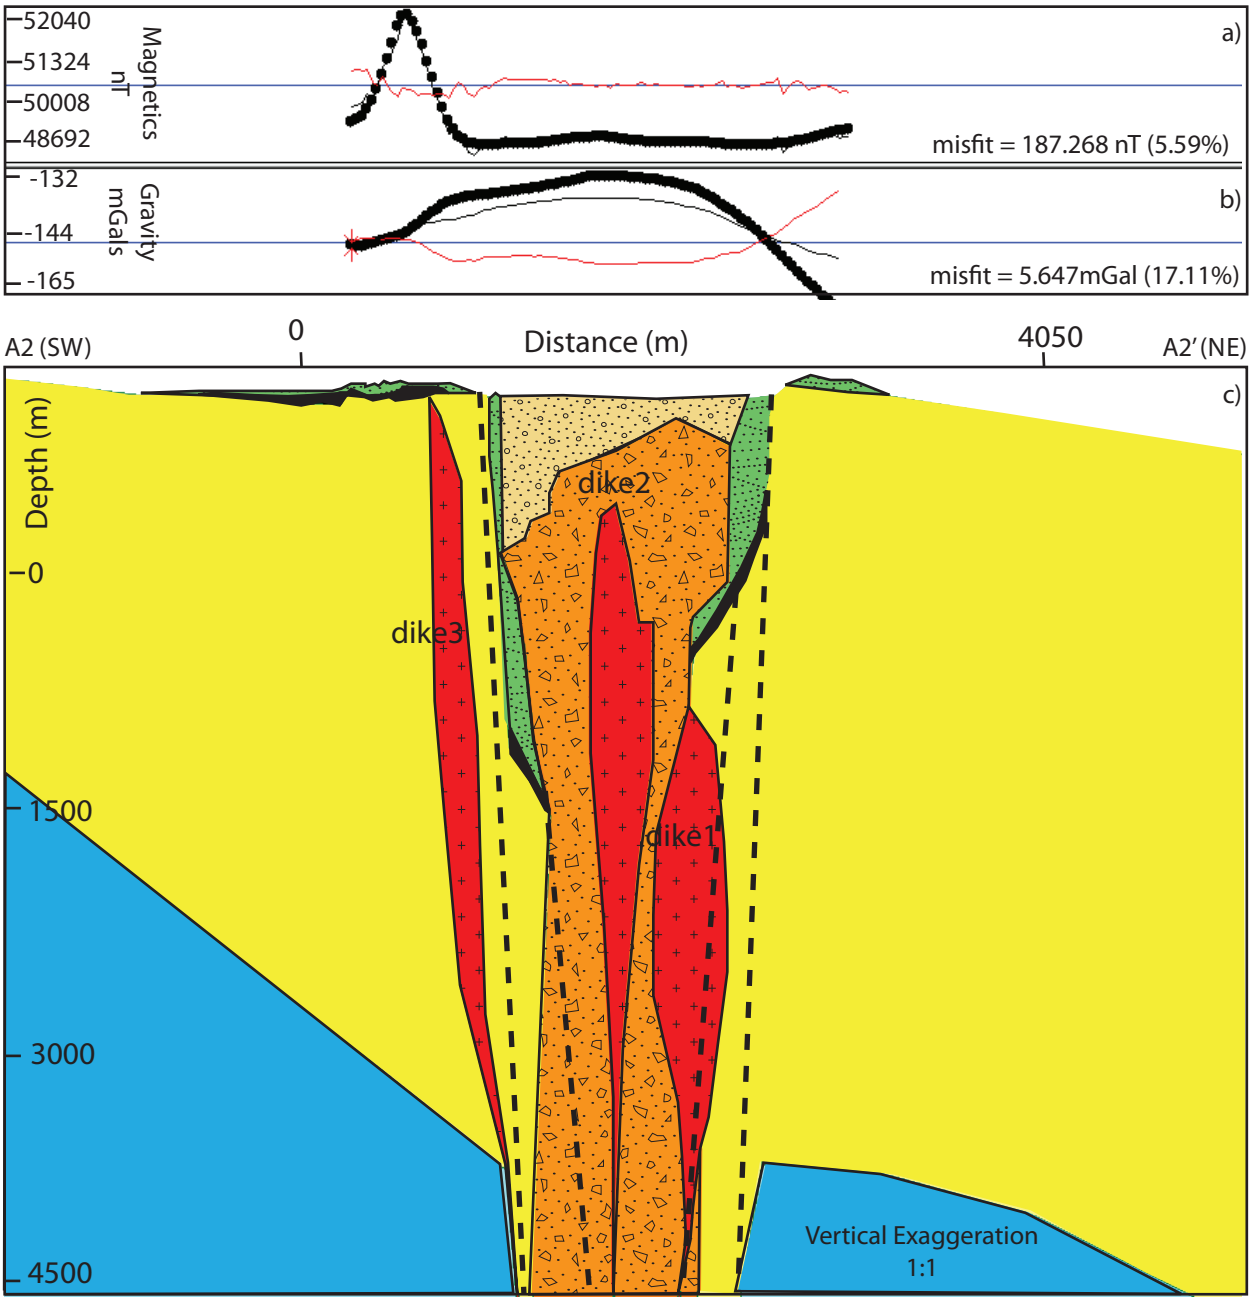

Figure 8. (a) 2D magnetic inverse model along transect A2-A2′ of Kibourne Hole from the reduced to pole magnetic anomaly map (Rhodes and Hurtado, 2012). (b) 2D gravity inverse model along transect A2-A2′ of Kilbourne Hole (our data). (c) Geologic cross-section of Kilbourne Hole arranged from south west to north east across Kilbourne Hole along transect A2-A2′. Location of along transect A2-A2′ is shown in Figure 5. This cross-section of Kilbourne Hole was developed using the two-dimensional integrated gravity and magnetic inversion method using our gravity and magnetic data. Density and magnetization constraints are given in Table 1. Dots are observed gravity values in b) and observed magnetic intensity in a). Black lines are the calculated gravity and magnetic anomaly. Red lines show the misfit values between the observed and calculated data. Dashed black lines in c) are the estimated locations of buriedfault zones from caldara-like collapsing of Kilbourne Hole after the eruption.

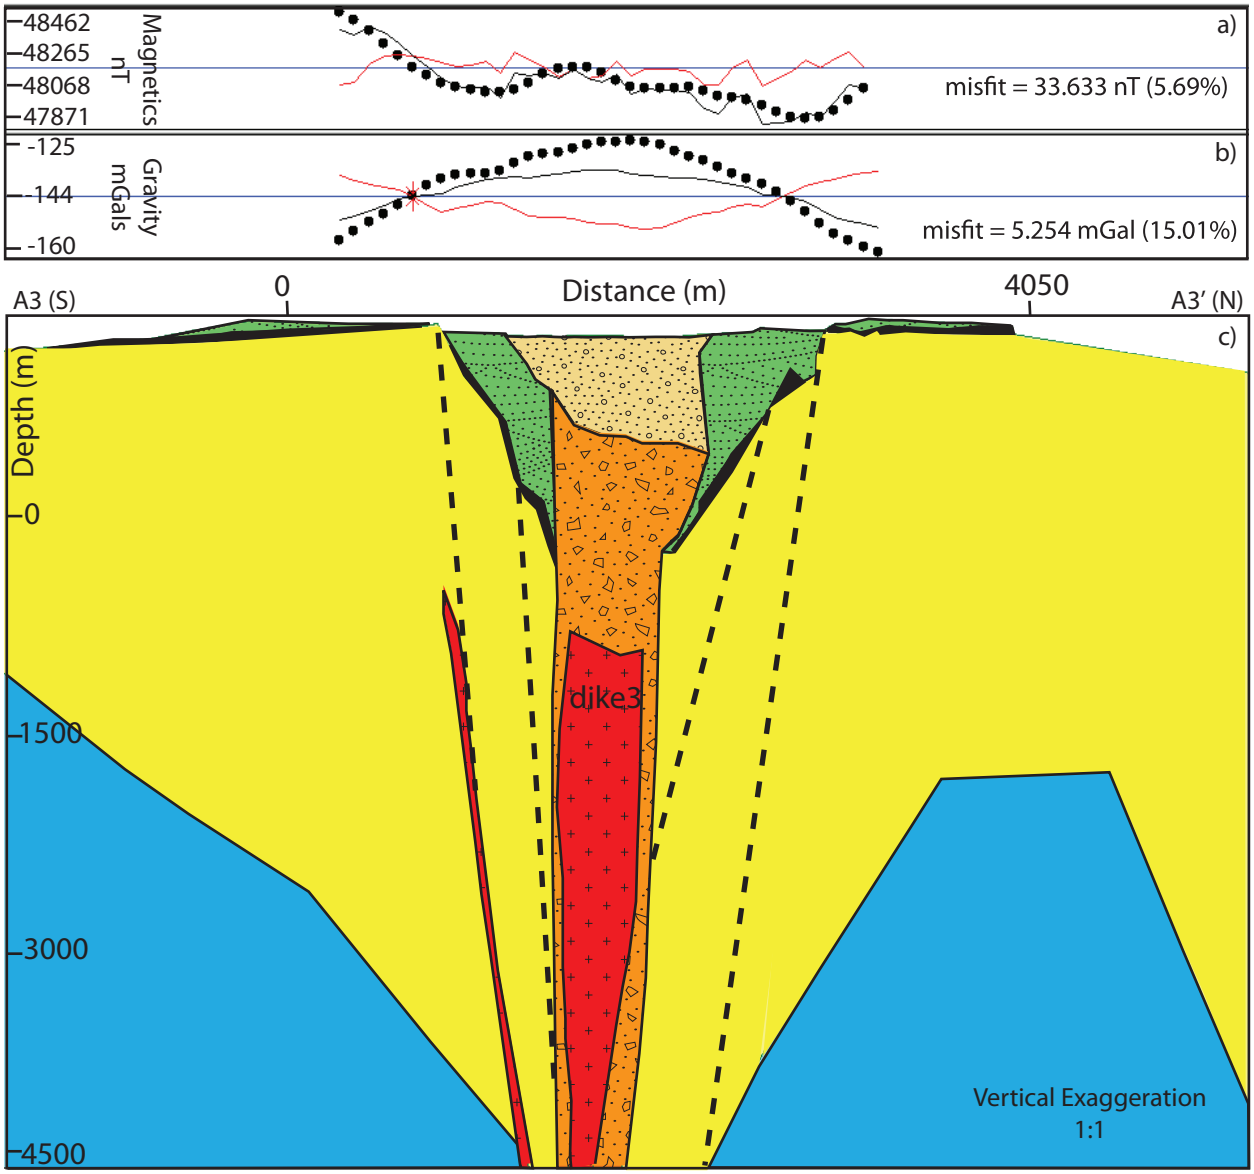

Figure 9. (a) 2D magnetic inverse model along transect A3-A3' of Kibourne Hole from the reduced to pole magnetic anomaly map (Rhodes and Hurtado, 2012). (b) 2D gravity inverse model along transect A3-A3' of Kilbourne Hole (our data). (c) Geologic cross-section of Kilbourne Hole arranged from south to north across Kilbourne Hole along transect A3-A3'. Location of along transect A3-A3' is shown in Figure 5. This cross-section of Kilbourne Hole was developed using the two-dimensional integrated gravity and magnetic inversion method using our gravity and magnetic data. Density and magnetization constraints are given in Table 1. Dots are observed gravity values in b) and observed magnetic intensity in a). Black lines are the calculated gravity and magnetic anomaly. Red lines show the misfit values between the observed and calculated data. Dashed black lines in c) are the estimated locations of buried-fault zones from caldara-like collapsing of Kilbourne Hole after the eruption.

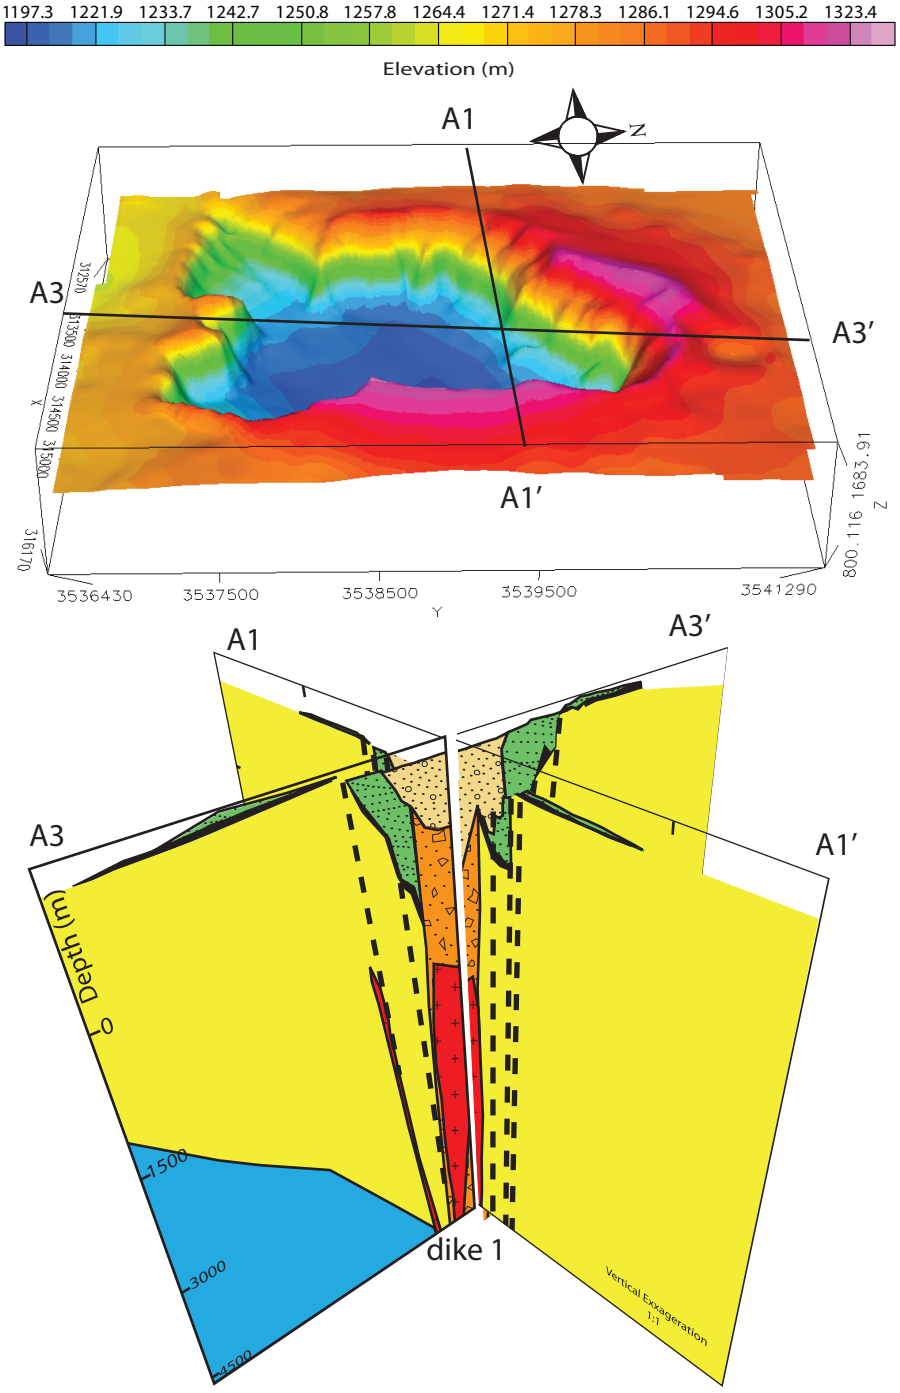

Figure 10. A fence diagram showing connectivity of dike 1 on cross-sections A1-A1′ and A3-A3′. The 3D perspective view of the surface topography of Kilbourne Hole is shown above the fence diagram for geographic context.

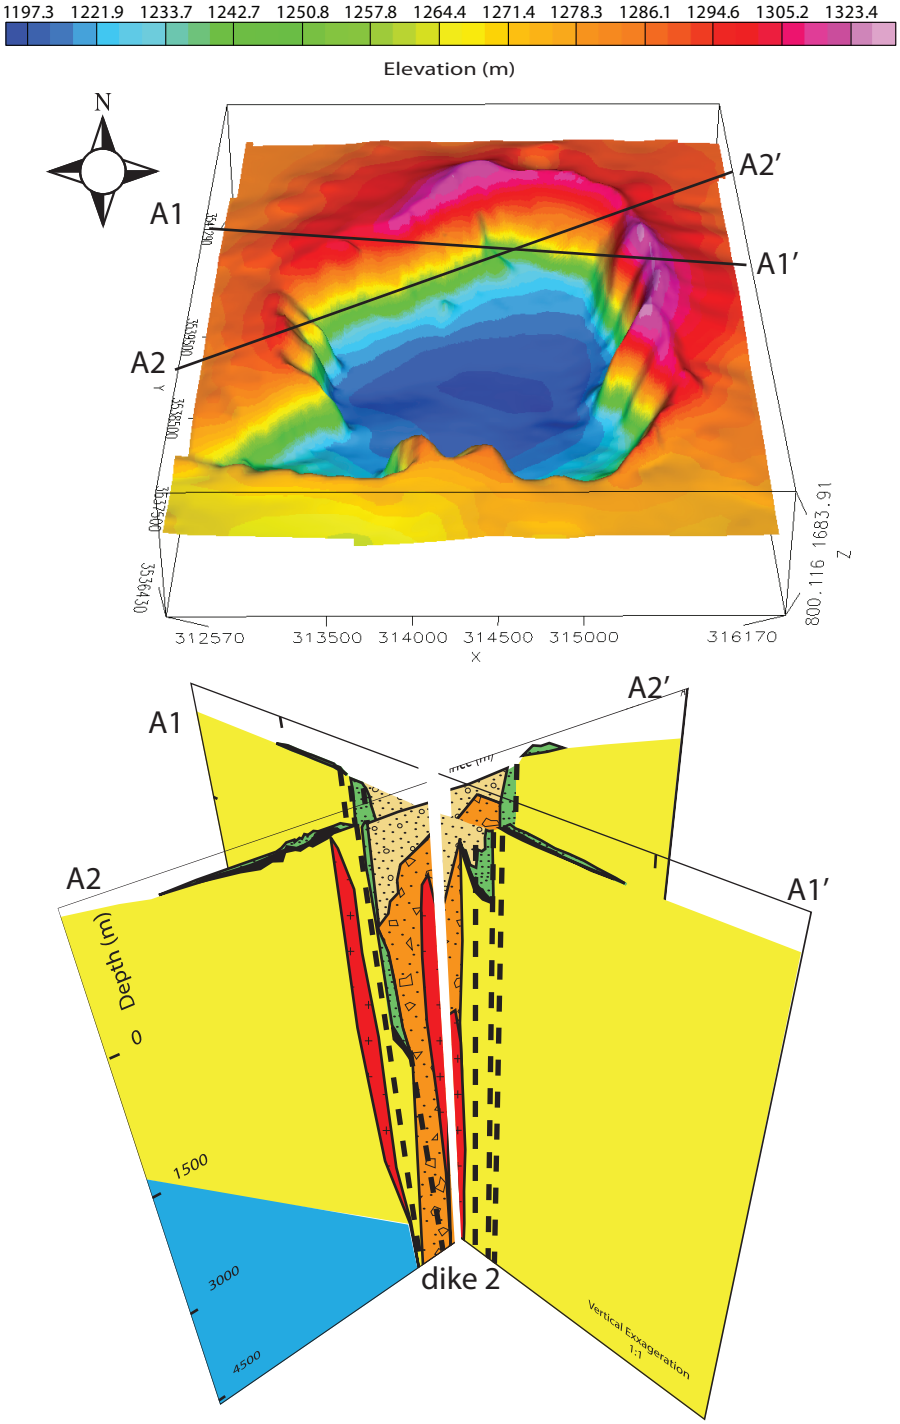

Figure 11. A fence diagram showing connectivity of dike 2 on cross-sections A1-A1′ and A2-A2′. The 3D perspective view of the surface topography of Kilbourne Hole is shown above the fence diagram for geographic context.

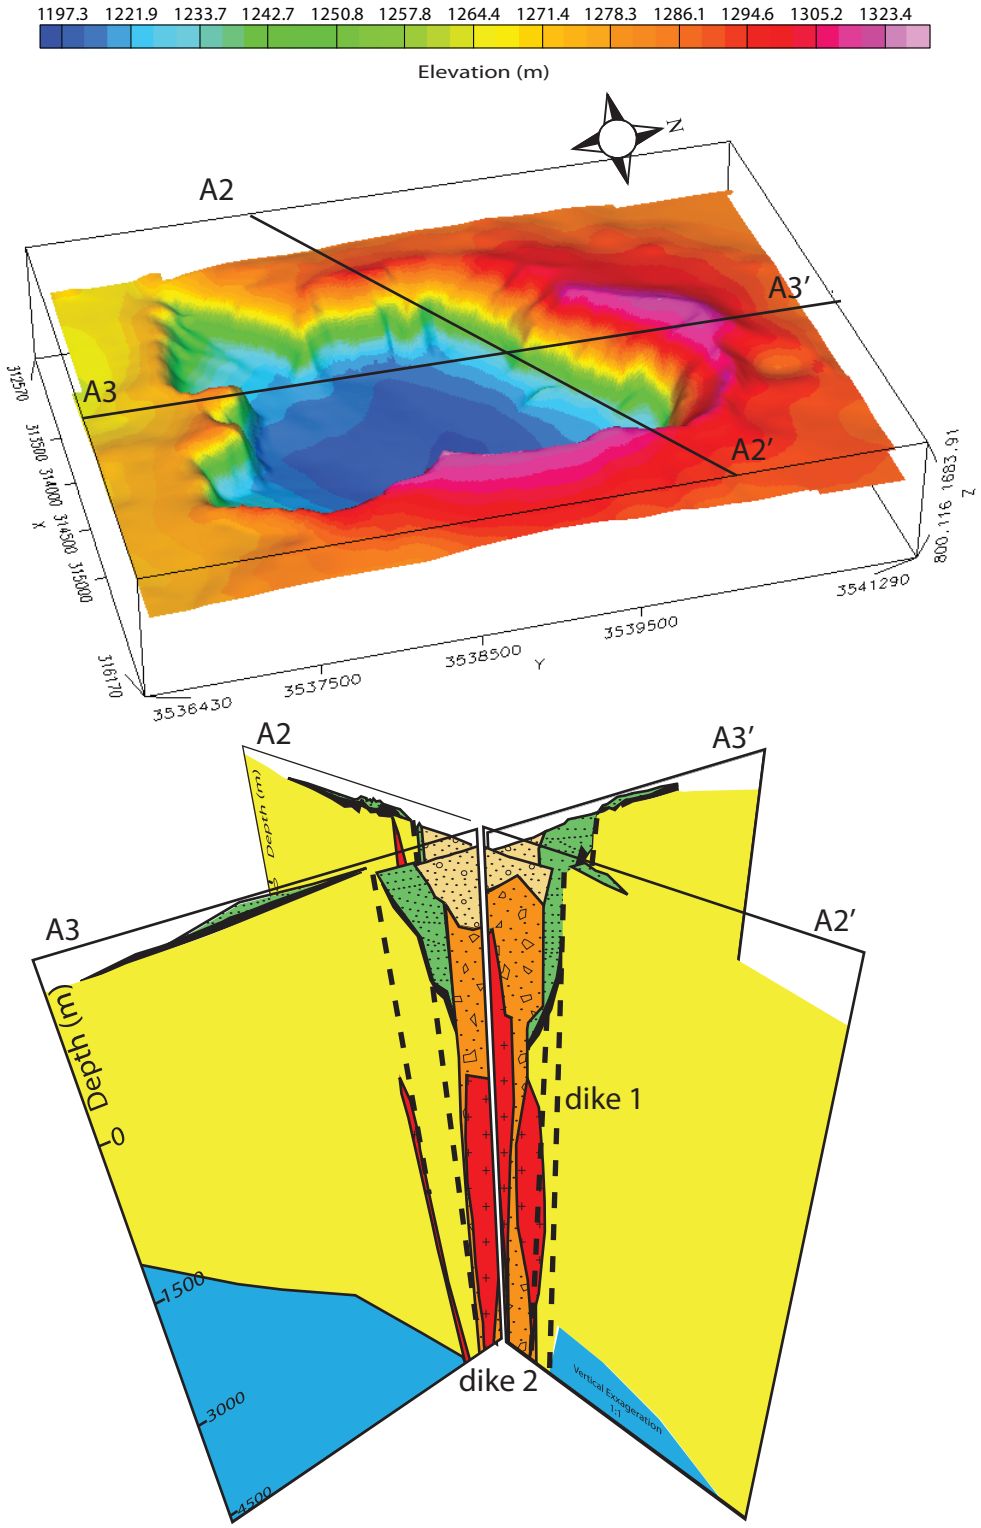

Figure 12. A fence diagram showing connectivity of dike 2 on cross-sections A2-A2′ and A3-A3′. The 3D perspective view of the surface topography of Kilbourne Hole is shown above the fence diagram for geographic context.

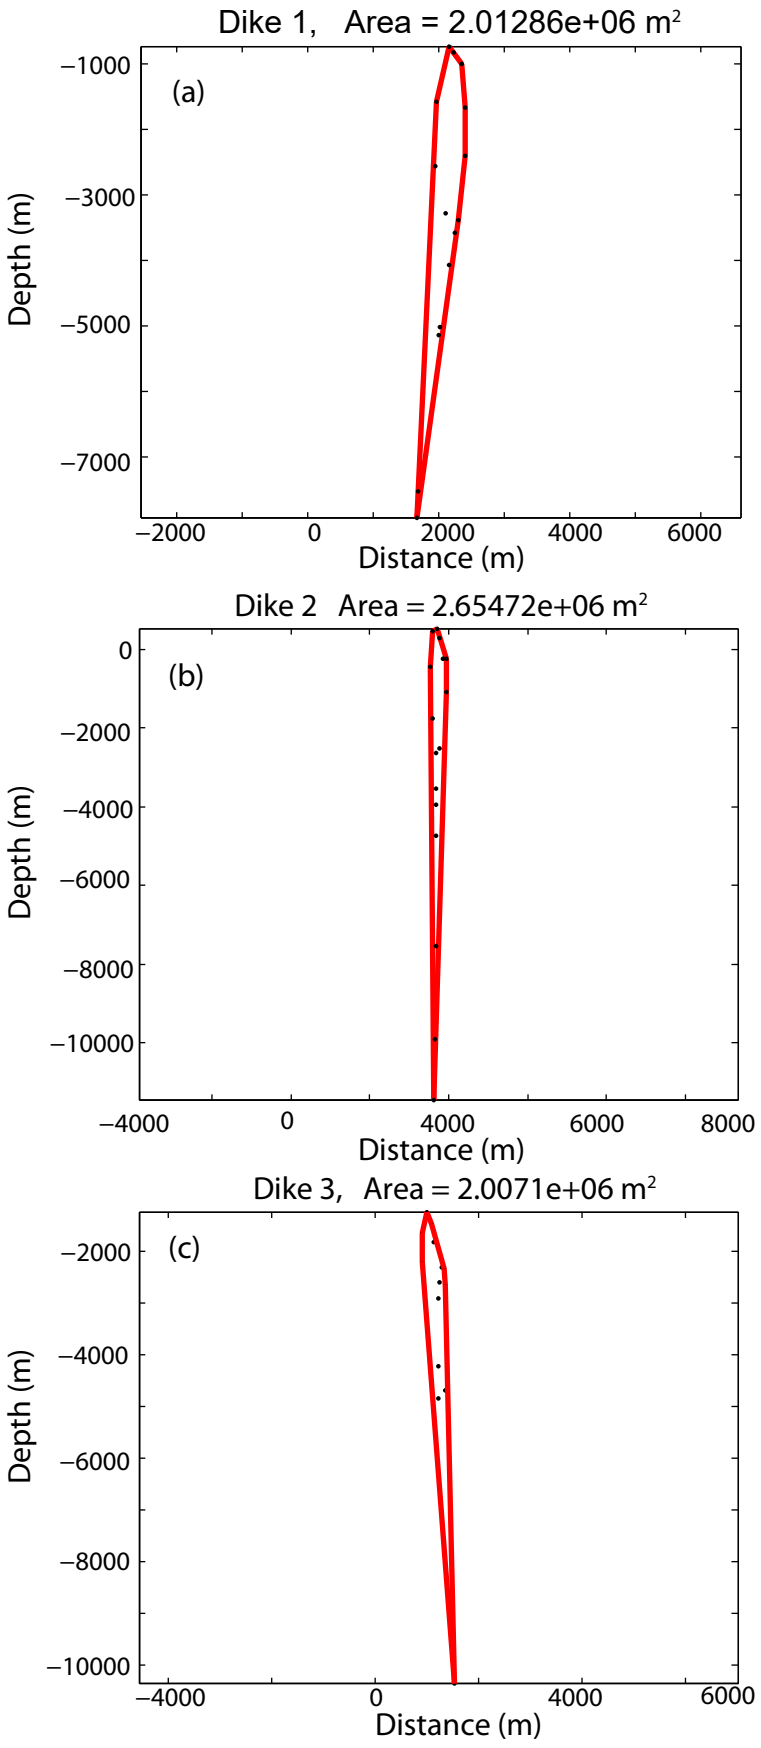

Figure 13. MAT LAB profiles of intrusion zones separated from integrated gravity-magnetic models of Kilbourne Hole. Black dots showed locations of where the intrusion zone appeared on the models. Red lines are the best fit geometrical shapes to the intrustion bodies generated by MAT LAB. The areas of intrusion zones were calculated using this overestimated-best fit of the geometrical bodies (red lines). In (a) profile of dike 1 derived from cross-section A2-A2′, (b) profile of dike 2 derived from cross-section A2-A2′, and (c) profile of dike 3 derived from cross-section A1-A1′.

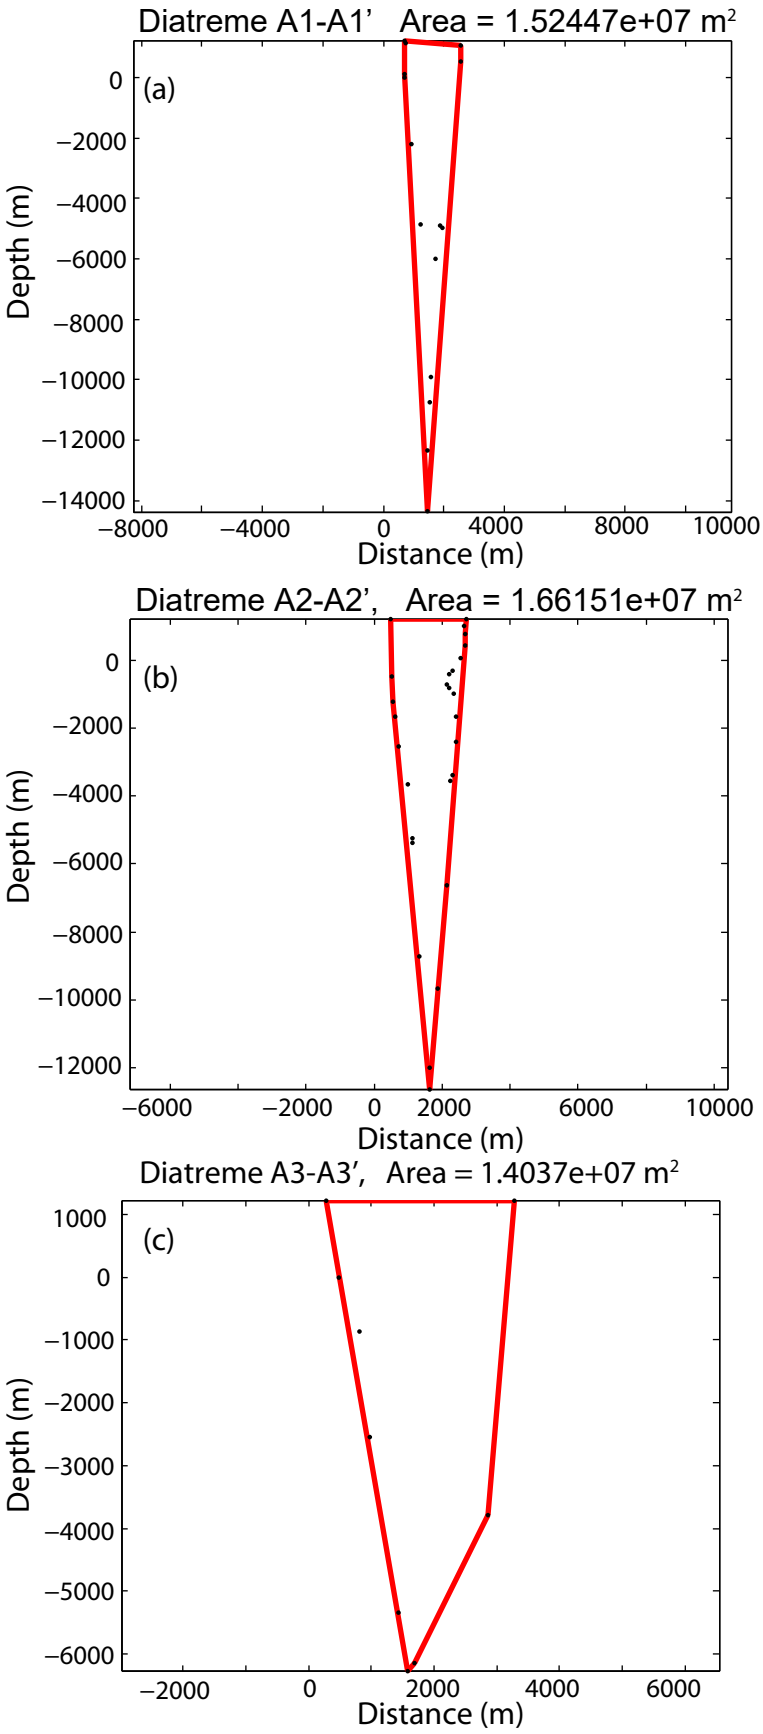

Figure 14. MAT LAB profiles of the diatreme separated from the integrated gravity-magnetic models of Kilbourne Hole. Black dots show locations of where the diatreme appeared on the models. Red lines are the best fit geometrical shapes to the diatreme bodies generated by MAT LAB. The areas of diatreme were calculated using this overestimated-best fit of geometrical bodies (red lines). In (a) profile of diatreme derived from cross-section A1-A1′, (b) profile of diatreme derived from cross-section A2-A2′, and (c) profile of diatreme derived from cross-section A3-A3′.

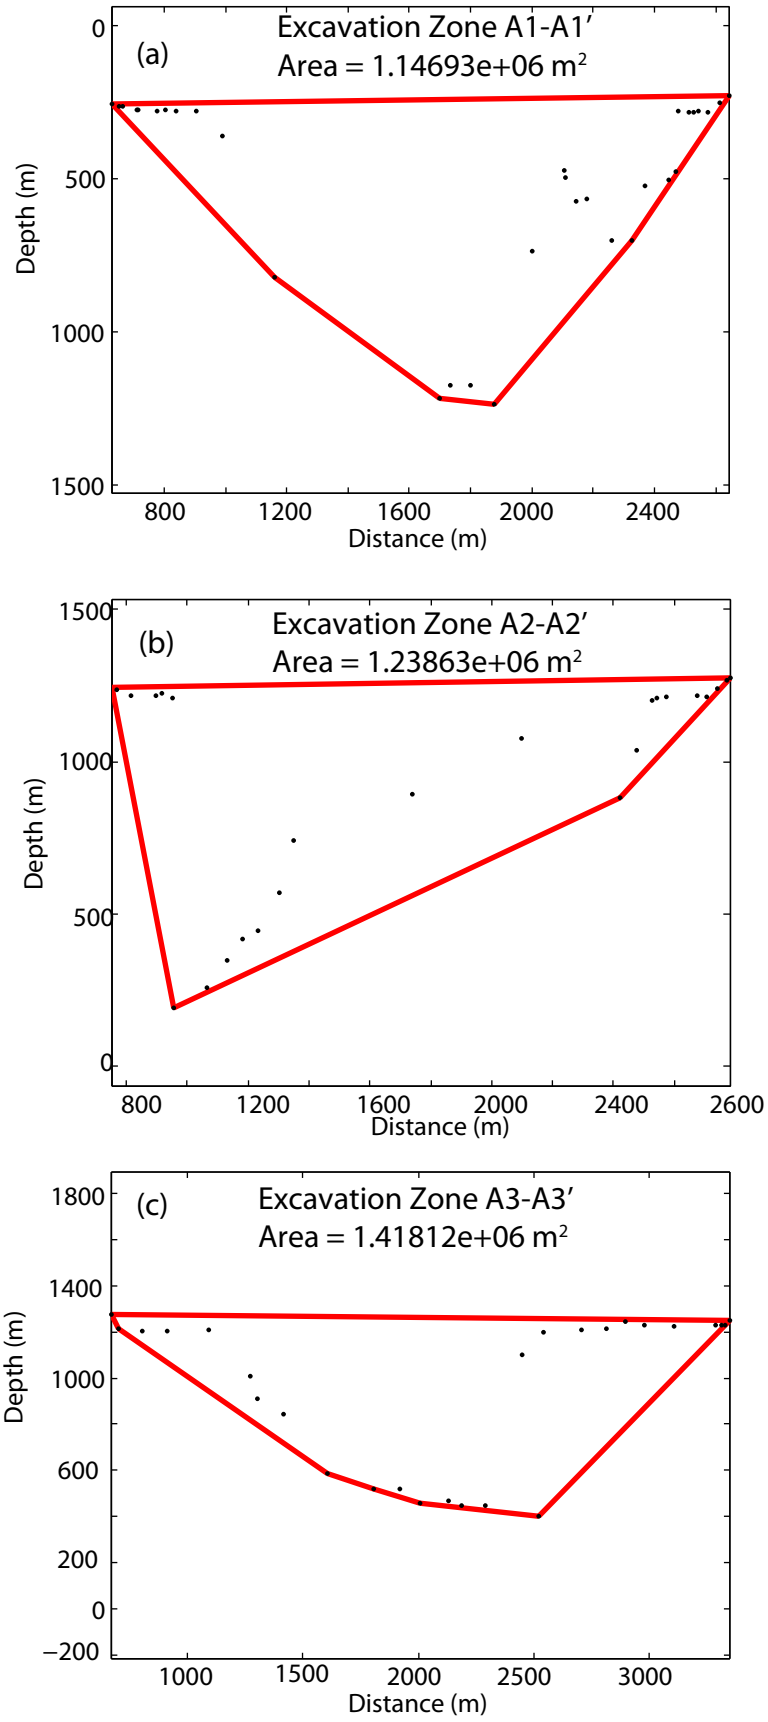

Figure 15. MAT LAB profiles of the excavation zone separated from the integrated gravity-magnetic models of Kilbourne Hole. The zone of excavation is considered to be the area of the present day crater and young alluvial material that is filling the crater. The bodies of young alluvial filling the crater are shown in all three models. Black dots show locations of where the excavation zone appeared on the models. Red lines are the best fit geometrical shape to the excavation zone generated by MAT LAB. The area of excavation zones were calculated using this overestimated-best fit of geometrical bodies (red lines). In (a) the profile of excavation zone derivedfrom cross-section A1-A1′, (b) profile of excavation zone derived from cross-section A2-A2′, and (c) profile of excavation zone derived from cross-section A3-A3′.

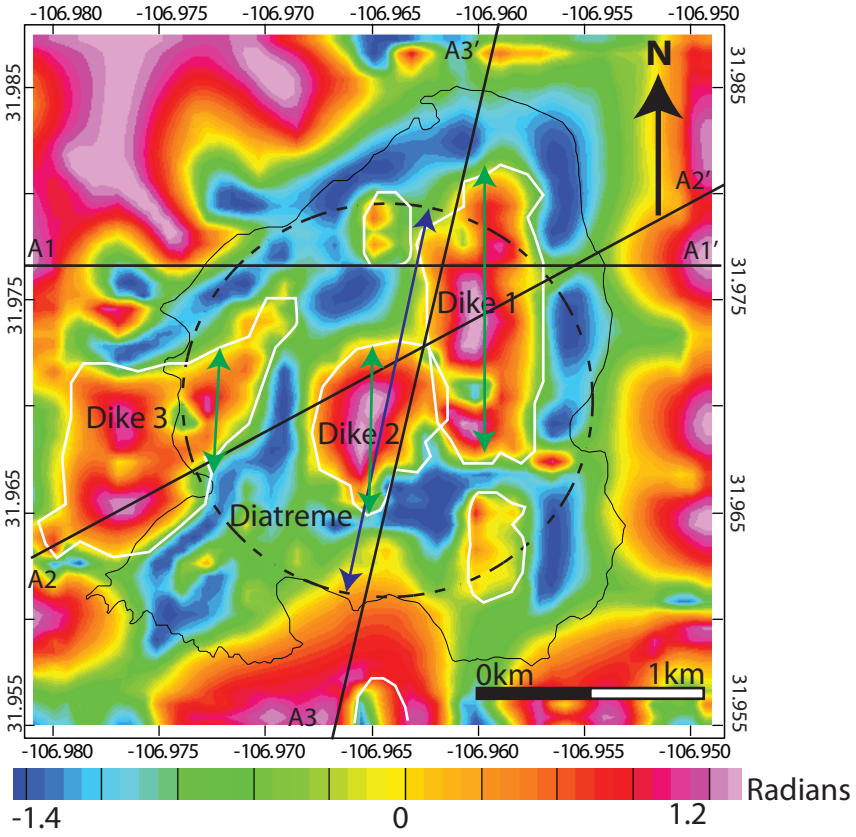

Figure 16. Edge detection results of magnetic anomalies on a tilt angle derivative map computed from the reduced to pole magnetic anomaly data for Kilbourne Hole (our data). White outlines show the boundaries of possible intrusion zones. Dashed circle is the best estimated boundary of the original crater at the time of eruption. Black lines are location of inversion models A1-A1′ and A2-A2′ and A3-A3′. Green arrows indicate the length of dike1, dike2, and dike 3. Blue arrow indicates the length of diatreme body, and excavation zone.

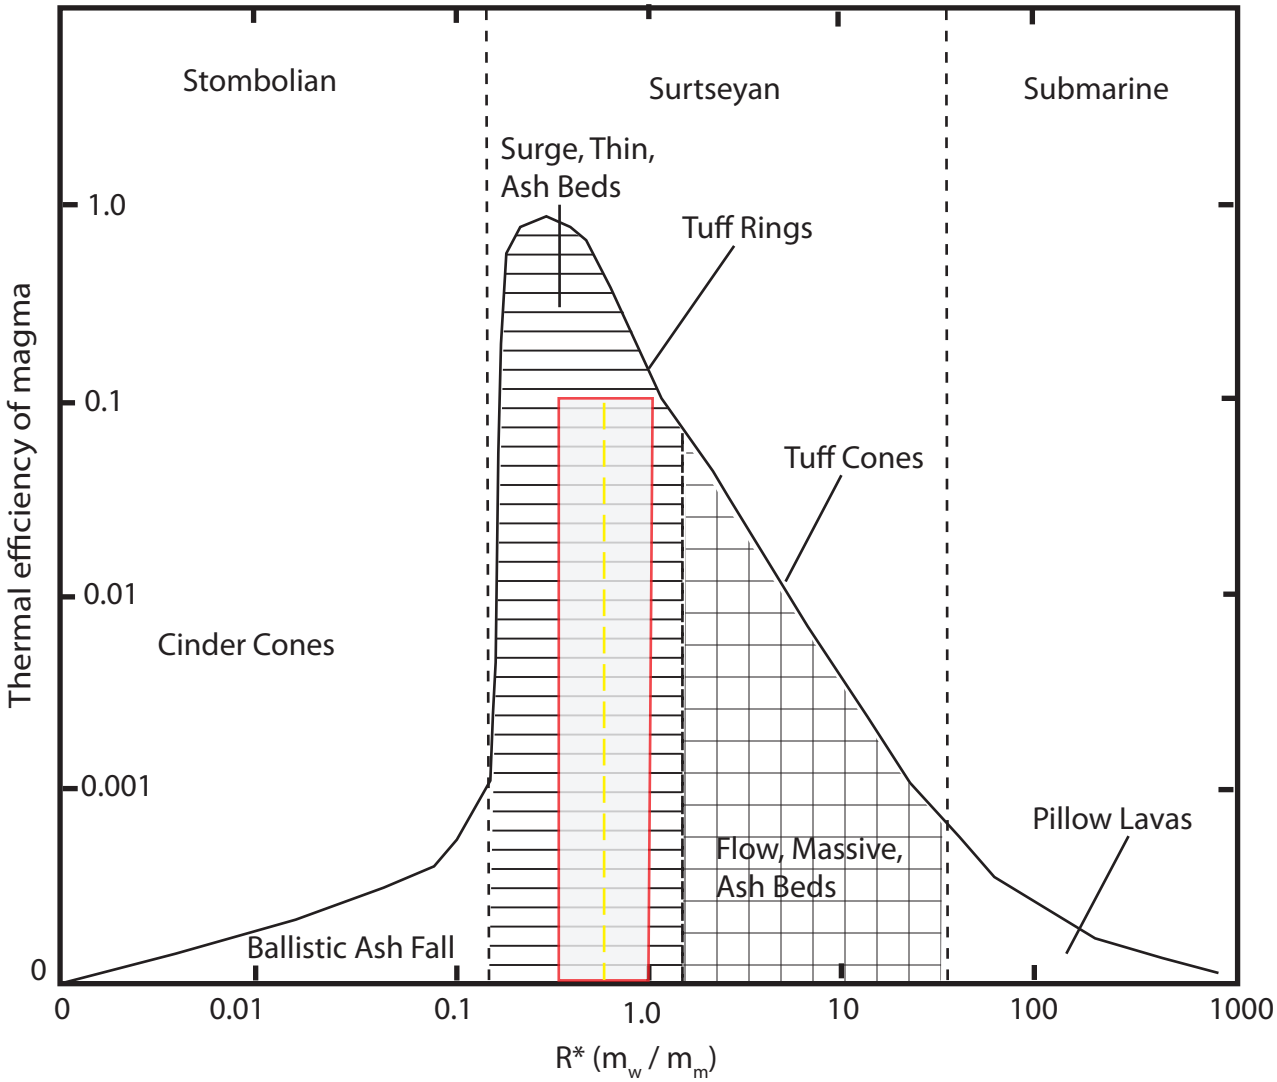

Figure 17. Ranges of thermal efficiency of phreatomagmatic eruptions shown as a function of water to magma mass ratio. Ranges are indicated types of eruptions (Strombolian, Surtseyan, and submarine) as well as the corresponding landforms and depositional facies (adapted from Wohletz and McQueen, 1984). Shaded red box indicates ranges of water to magma mass ratio (0.79 ± 0.23) predicted for Kilbourne Hole eruption.

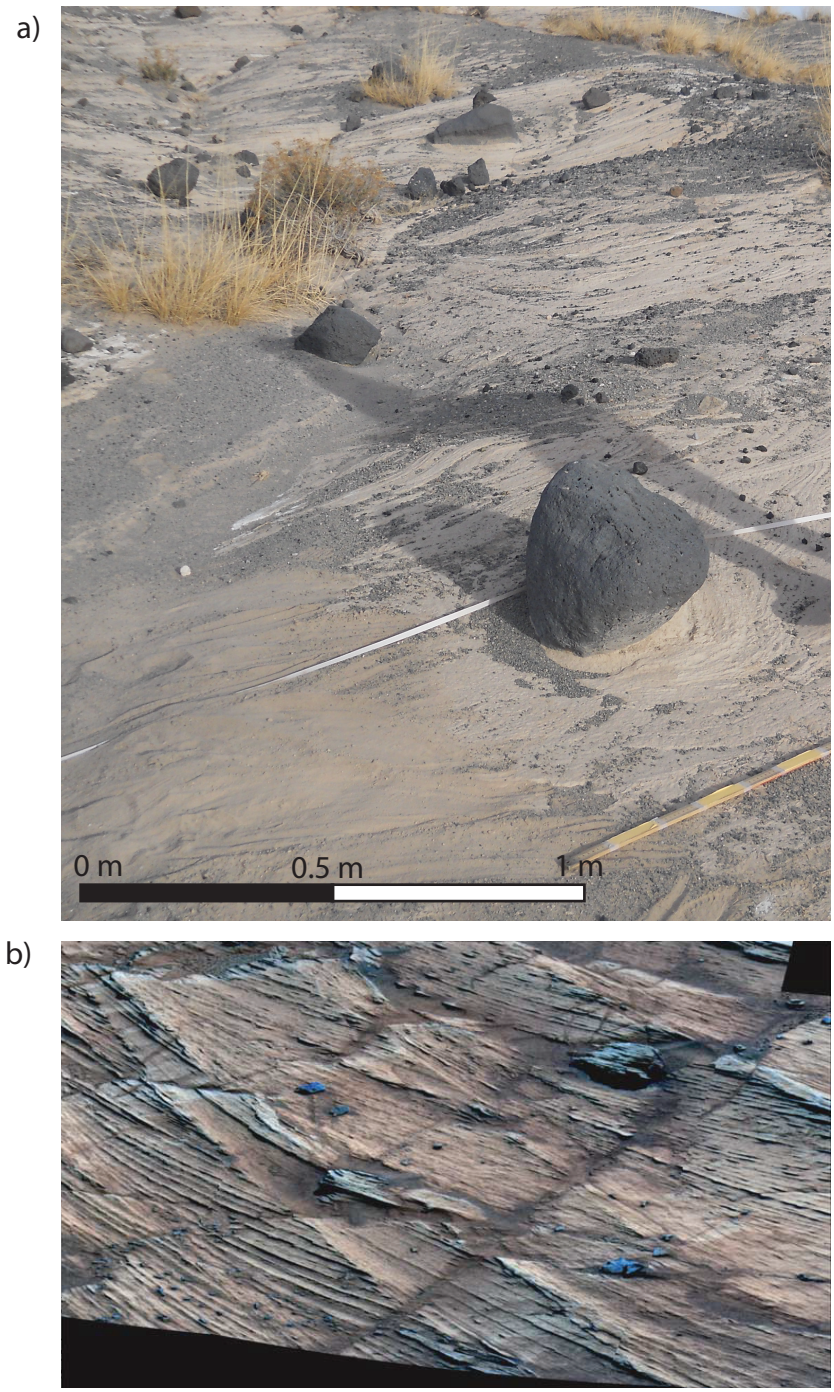

Figure 18. (a) Cross bedded tuff ring, volcanic blocks, and volcanic sags found on the west rim of Kilbourne Hole. The image is a true color photograph taken by the authors in November 2014. (b) High-angle cross bedding, volcanic blocks, and volcanic sags found on Home Plate, Mars. The mosaic image is a false color stretch photograph. The horizontal distance across the lower part of both images is approximately 1.5 m. (mosaic credit Squyres et al., 2007).

Appendix A: Kilbourne Hole Gravity Survey Data and Data Correction

A total of 172 gravity readings from Kilbourne Hole are included in this appendix. In this appendix, all the data and data corrections are displayed in an excel spreadsheet file. Field data collected for gravity station include latitudes, longitudes, the gravity meter reading from the Lacoste and Romberg G-30 unit, and elevation measurement from the Topcon GB-1000 unit. All gravity readings from Lacoste and Romberg G-30 unit are adjusted for the dial constant (LaCoste and Romberg, 2004). Corrected data also included in this appendix are: (1) terrain correction, (2) tidal drift correction, (3) atmospheric correction, 4) free-air correction, and 5) Bouguer correction using a reduce density of 2670 kg/m^3. The formula and constants used in our data correction process are based on Briesacher et al. (2002) and Hildenbrand et al. (2002).

Appendix B: Kilbourne Hole Reduced to Pole Magnetic Data

In this appendix B, we include our reduced to pole magnetic data from Kibourne Hole in an excel spreadsheet. The reduced to pole magnetic data were derived from a total of 166 magnetic measurements form our field magnetic surveys at Kilbourne Hole. Our magnetic field works were completed over 1 year time span with surveys in March, 2011, May 2011, and January 2012 (Rhodes and Hurtado, 2012). We used the reference total magnetic field derived by Finlay et al. (2010) and corrected our field magnetic data to the reduced pole magnetic data using the `RTP` extension implemented in the *Geosoft Oasis Montaj 6.0* software suite. The spreadsheet include: (1) latitudes, (2) longitudes, and (3) the reduced to pole magnetic intensity value in (nT).

Appendix C: Area of Polygon Calculation

Included in Appendix C is a computer code we used to estimate the area of geometrical bodies from the inversion model. The code was written for MATLAB R.2012b. We adopted a procedure developed by Lundgren (2005). The input data for this code routine is an excel file containing x and z coordinate vector of the polygon of interest. The output of this code yields a resulting vector including: (1) the radius of the best fit, (2) the area of the best fit polygon.

Appendix D: Volume and Mass Estimation

Included in Appendix D is an excel spreadsheet we use to calculate the volume and mass of volcanic dikes, the diatreme and, the excavation zone. Using Equation 8 (see Chapter 2) implemented in this excel spreadsheet, we also calculated mass of water and the ratio of mass of water to mass of magma. The input of this spreadsheet are area of polygon obtained from Appendix C, the initial velocity from Chapter 3, rock density (table 1; see Chapter 2), and temperature and atmospheric pressure constants (Wohletz, 1986). The uncertainties of each variable are also propagated into the final result. The methods used in error and uncertainty analysis are form Taylor (1997) and Bevington and Robinson (2002). The formula used in our error and uncertainty analysis is also implemented in third page of this excel spreadsheet. The output products of this spread sheet are 1) mass of water, 2) mass of water to mass of magma ratio, and 3) volume and percent of water in groundwater reservoir, 4) the uncertainties of the obtained variables.

Abstract

We hypothesize that the sizes of volcanic blocks ejected by a phreatomagmatic eruption are indicative of explosion behavior and characteristics of the groundwater reservoir involved. In this research we develop a non-invasive geophysical survey technique using ground-penetrating radar (GPR) to quantitatively map the size distribution of volcanic blocks and sags at an analog phreatomagmatic volcano site with the goal of understanding the hydrologic conditions that were involved in its eruption. We determined the distribution of volcanic block sizes as a function of radial distance from the crater rim at Kilourne Hole, NM using GPR. We collected the size distribution of volcanic blocks along six survey transects, and estimated that volcanic blocks were ejected by the Kilbourne Hole eruption at an initial velocity of 123 ± 9 m s^{-1} and that the duration of the gas expansion phase of the eruption was as long as 92 ± 11 s. The initial pressure inside the vent at the time of eruption was 163 ± 9 bar. Using an empirical relationship between the maximum gas expansion velocity and the initial pressure, we estimate that the ratio between the mass of gas and the mass of solid material that was released during the eruption was 0.01-0.02 (1-2%). Assuming that the all gases were

derived from groundwater, we applied this gas-to-rock mass ratio to the independent estimates of the mass of ejected volcanic fragments and determined the amount of water involved in the Kilbourne Hole eruption. Our results suggest that the mass of water in the Plio-Pleistocene groundwater reservoir that fed the Kilbourne Hole contained a minimum of $7.7 \pm 1.0 \times 10^9$ kg (~ 0.008 kg^3) of water. We have successfully utilized geophysical mapping results of phreatomagmatic outcrop as climate proxies. The implication of our geophysical approaches for planetary exploration is also discussed.

1. Introduction

The search for water on Mars has focused mainly on surface water, ice water, or groundwater (Ezell and Ezell, 2013, Hobbs et al., 2015, Marra, 2015). Observations indicate that rivers and groundwater may have been prominent features in its early history (Marra, 2015). Features such as Home Plate plateau, a suspected remnant of a phreatomagmatic eruption located in Gusev Crater on Mars (Squyres et al., 2007), can reveal important information about paleohydrologic conditions. When magma interacts with a groundwater source, a phreatomagmatic eruption can occur. The resulting explosion can be so strong that it excavates a volcanic crater (Wohletz and Sherridan, 1981) and creates a high volume of pyroclastic material (Wilson and Head, 1994). The existence of phreatomagmatic features like Home Plate on Mars implies the existence of groundwater in the past (Squyres et al., 2007). In a phreatomagmatic eruption, the heated water will flash into steam, which, if confined, will build up pressure, potentially to the point of explosive release. The resulting explosion will excavate a crater and eject pyroclastic material (Wohletz and Sherridan, 1981). Because the initial gas ejection velocity is the direct result of the water vapor pressure trapped inside the volcanic vent, it can be used to determine the size of the groundwater reservoir that interacted with the magma source. Knowledge of the physics governing phreatomagmatic eruptions offers a unique opportunity to make quantitative estimates of the amount of water involved. To be able to quantify the amount of groundwater involved in the early volcanic activity on Mars is the goal of this research.

In this research, we hypothesized that the size distribution of pyroclastic material ejected by a phreatomagmatic eruption is indicative of the behavior of the explosion and

the characteristics of the groundwater reservoir involved (Wohletz and Sheridan, 1983). To test the hypothesis, we mapped the radial size distribution of volcanic blocks ejected from Kilbourne Hole using a GPR. The radial size distributions of volcanic blocks data were used to determine the initial gas ejection velocity (Fagents and Wilson, 1996; Wilson, 1999; Sparks, 1976; Wilson, 1972). We present here the results of a GPR study of a phreatomagmatic volcano – Kilbourne Hole in New Mexico – designed specifically to decipher the paleohydrogeological conditions at the time of eruption. The techniques used in this research can serve as an analog for similar studies applied to the paleohydrologic exploration of other planets, like Mars. Our GPR surveys were designed specifically to work on a phreatomagmatic setting as an implication to future Mars exploration. The majority of the Martian surface has been shaped by extensive volcanism (Tanaka et al., 1992; Mouginis-Mark et al., 1992). The accumulated fine-grained material from volcanic activity on Mars resembles terrestrial volcanic ash on Earth (Grant and Schultz, 1990). The fine-grained materials from volcanic activity on Mars are distinguished by their easily eroded surfaces, their low thermal inertia, and continuous, regular layering that are similar to terrestrial sedimentary deposits (Grant and Schultz, 1990; Tanaka, 2000). Because of this similarity, we first designed a GPR study on an analog phreatomagmatic volcanic site on Earth and then later we can potentially adapt our survey design on the Martian site. To evaluate the potential of future GPR investigations on Mars, we designed medium-frequency (250 MHz) GPR surveys to map volcanic block size distribution at Kilbourne Hole, NM. The implications of these integrated surveys for the exploration Mars are to improve the ability to characterize volcanic activity on Mars and to quantify the amount of Martian ancient groundwater.

We performed an experiment at an analogous site to determine the relationship between the volcanic block size distribution and the terminal velocity of the volcanic clasts that were dropped at the time of eruption. We then used the obtained relationship to determine the following: the initial velocity of eruption, the time duration of the eruption phase, the initial vent pressure at the time of eruption and the amount of groundwater that fed the eruption. In this paper we describe: (1) our strategy for imaging and measuring the sizes of volcanic blocks and associated sags from GPR profiles; (2) how to quantify the initial gas ejection velocity based on the size distribution of volcanic blocks; (3) a method for calculating the volume of the groundwater reservoir that fed the Kilbourne Hole eruption; and (4) the use of GPR for similar applications in planetary exploration.

One obstacle that could prevent GPR and other electrical surveys on Mars to become successful is that the application of electrical techniques on the Martian subsurface heavily depends on the knowledge of the subsurface electromagnetic characteristics and how these will affect wave propagation (Wainstein et al., 2008). As such, further investigations and other complimentary approaches on Martian subsurface electrical properties are still required to adapt Earth techniques to properly work under Martian conditions (Wainstein et al., 2008).

2. Background

2.1 Phreatomagmatic Volcanoes on Earth and Mars

A phreatomagmatic eruption is caused by the explosive interaction between rising magma and an external source of water such as groundwater, surface water, seawater, meteoric water, hydrothermal water, ice-melt water, or lake water (Morrissey et al., 2000;Wilson and Head, 2003). Prior to the eruption, vapor produced by heating the water source can be trapped, building up tremendous gas pressure. The trap can be a cap of resistant rock, for example a lava flow, overlying a groundwater reservoir. As gas accumulates in the confined aquifer beneath the cap rock, the pressure rises. Once the pressure exceeds the tensile strength of the cap rock, an explosive release of the pressurized gas can occur. Water heated by lava then flashes in steam and expands violently; fragmenting the magma it is in contact with into fine-grained ash. As the gas radially expands from the vent, it pushes the cap rocks and other solid material outward with it. The style of phreatomagmatic eruptions range from relatively mild inflows of low viscosity lava into a lake or the ocean to form pillow lavas to extremely high-energy explosions that produce pyroclastic deposits consisting of more than 90% fragmented country rock (Wohletz and Zimanowski, 2000). The resulting eruptive products can include airfall tephra (e.g. ash and pumice), ejected volcanic blocks, pyroclastic flow-and-surge deposits, and debris flows (Barberi et al., 1989). Landforms produced by phreatomagmatic eruptions include the excavated crater, called a maar, and a surrounding tuff ring or cone (White and Ross, 2011). Tuff cone, mainly composed of thick-bedded pyroclastic flow and surge deposits, are characterized by high profiles feature and steepness of the bedding (>25 degrees). Wetter eruptions (with a water-rock ratio >1)

result in larger diameter tuff rings and tuff cones than those that formed by dryer eruptions (Wohletz and Sherridan, 1981). A tuff ring is formed from an explosion at a shallower depth (less than 0.5 km) than a tuff cone. Tuff ring mainly composed of thin-bedded pyroclastic flow and surge deposits and characterized by low profiles features and less steepness of the bedding <10 degrees). Wohletz and Sherridan (1981) suggest that fluid dynamic interactions between groundwater and magma control the strength of the resulting volcanic eruption.

Pyroclastic surge deposits are similar to pyroclastic flow deposits in composition, except that surge deposits are generally richer in lithic fragments than flow deposits and are better sorted. Both pyroclastic surge and flow deposits are derived from ignimbrite or deposited during the same ignimbrite-forming eruption (Fisher and Heiken, 1982). The pyroclastic deposits produced by a phreatomagmatic eruption often contain ejected blocks of basalt and other lithologies measuring up to 1 m or more in diameter (Walker and Groasdale, 1971). These volcanic blocks were ballistically ejected from the vent at the time of eruption and, when they land, they deform the unconsolidated pyroclastic deposits into asymmetric depressions called sags. The asymmetry of the sag can be used to determine the trajectory of the blocks and the location of the vent (Walker and Groasdel, 1971). Volcanic sags on Earth typically indicate that the deformed pyroclastic deposit were unconsolidated and wet at the time it was bombarded by the volcanic blocks.

What has been interpreted to be an outcrop of material deposited by a phreatomagmatic eruption was identified by the Mars Exploration Rover Spirit at Home Plate Plateau in Gusev Crater, near the Martian equator (Squyres et al., 2007). Squyres et

al. (2007) interpreted that the layers at Home Plate are composed of clastic rocks of moderately altered alkali basalt composition and suggested that Home Plate is a result of a phreatomagmatic activity that occurred when the alkali-rich basaltic magma came into contact with a subsurface fluid. The stratigraphically lowest unit at Home Plate is likely pyroclastic material, while the uppermost unit represents eolian reworking of those pyroclastic materials (Vaucher et al., 2009). In the lower unit, cross-stratified surge deposits are found which contain what are interpreted to be volcanic blocks and sags (Squyres et al., 2007). The chemical composition of the volcanic blocks is similar to those of basalts that are found nearby and suggest that the deposits lay close to the source vent (Squyres et al., 2007).

Ennis et al. (2007) compared the stratigraphy at Home Plate to that at Zuni Salt Lake, a phreatomagmatic crater in Arizona, and found some similarities between the two sites, including: (1) both have tephra layers with low-angle cross bedding; (2) both show occurrences of volcanic ejecta impacting wet cohesive tephra beds, producing sag features; and (3) both are capped by massive basalt blocks. One difference between the sites is that the bedding at Home Plate dips 6°, whereas the bedding at Zuni Salt Lake dips more steeply (25°). Ennis et al. (2007) suggested that under the weak gravity field and thin atmospheric pressure on Mars, the ash ejected from a phreatomagmatic eruption would be expected to be more widespread and to have shallower dips. Because no evidence of surface excavation, collapse, or slump features have been found at Home Plate, Ennis et al. (2007) suggested that Home Plate is a phreatomagmatic volcano with a shallower basaltic source than that which produced Zuni Salt Lake.

2.2 Previous Geophysical Study on Mars

Among the previous the design of geophysical research on Mars (Picardi et al., 2004; Seu et al., 2007; Hamran et al., Kobayashi et al., 2014; 2015), ground-penetrating radar (GPR) is a popular method for its mobility and its applications on ground ice and permafrost material (Picardi et al., 2004; Seu et al., 2007). There are several types of GPR equipment that have been deployed on Mars and the Moon. The Shallow Subsurface Radar (SHARAD) on board the Mars Reconnaissance Orbiter has probed the Martian subsurface to a depth of about 1 km (Hamran et al., 2015; Seu et al., 2007). The lower-frequency Mars Advanced Radar for Subsurface and Ionosphere Sounding (MARSIS) instrument is orbiting Mars surfaces on Mars Express satellite (Picardi et al., 2004). The Moon's Lunar Radar Sounder (LRS) was also installed and orbited on a Kaguya lunar exploration platform in 2007. LRS operated in a frequency range of 4-6 MHz. It provides 150 m resolution and ~5 km depth of penetration (Kobayashi et al., 2014). A ground-based GPR unit will be boarded on the NASA Mars 2020 rover mission. This ground-based radar will operate at 150-1200 MHz frequency and is using an ultra-wide band with bow-tie slot antenna at 60 cm above the ground surface. Depending on ground conditions, this radar will have the ability to penetrate to more than 10 meters depth.

2.3 Ground-Penetrating Radar

Ground-penetrating radar (GPR) is a non-invasive geophysical tool that has been used primarily for subsurface stratigraphic studies (e.g., Beres, and Haeni, 1991; Bristow

and Jol, 2003; Coma et al, 2005; Barone et al., 2007; Ferguson and Piece, 2012). GPR uses microwave frequency electromagnetic waves to probe the subsurface.

Most of the successful GPR surveys on Mars have been done in Martian polar ice (Hamran et al., 2015; Seu et al., 2007). The Shallow Subsurface Radar (SHARAD) on board the Mars Reconnaissance Orbiter has probed the Martian subsurface to a depth of about 1 km using a 20 MHz center frequency and 10 MHz bandwidths (Hamran et al., 2015; Seu et al., 2007). A GPR unit is comprised of a pair of antennas, a transmitter that emits electromagnetic waves into the subsurface, and a receiver that records the returned signal. When the transmitted radar signal encounters inhomogeneities in subsurface dielectric properties, some of the energy is reflected or scattered back to the surface and the receiver. In addition, the characteristics of the transmitted radar signal (e.g. polarity, phase, etc.) can change as it interacts with and is reflected by materials in the subsurface. The GPR receiver amplifies and records the returned radar signal detected at the surface. The recorded radar signals can be processed and displayed as an image called a radargram (Figures 3, 4, and 6).

For a stratigraphic layer that has homogenous dielectric properties, the reflected electrical wave is strong and continuous and is seen in a radargram as a bright continuous line called "a reflector" (Beres, and Haeni, 1991). For an inhomogeneous or poor sorting stratigraphic layer, the reflected wave is scattered and weak and may not be seen on the radargram. In nonmagnetic and homogeneous geologic media, radar waves travel at a velocity (v) that is a function of electrical permittivity (ε) (Thomson et al., 2012):

$$v = \frac{c}{\sqrt{\varepsilon}} \qquad (1),$$

where c is the velocity of radar waves in free space (0.2998 m/ns in a vacuum; Grote et al., 2003). The velocity can be used to determine the depth to the reflector, z (in m), using (Thomson et al., 2012):

$$z = \frac{Tv}{2} \qquad (2),$$

where T is the two-way travel time (in ns). To accurately calculate depth, however, a detailed velocity model is required, but it is difficult to derive such a velocity model because most geologic media is highly variable and inhomogeneous. For example, variations in moisture content can greatly attenuate radar waves (Russell et al., 2013). A solution to this problem is to directly measure the velocity of radar waves in situations where the depth of the reflector is known, i.e. using Equation (2) instead of Equation (1) to solve for v. As the radar wave propagated into the medium, the signal can be absorbed, lost, or attenuated. The rate of signal attenuation (β) significantly depends on mineral composition of the geological layer such as the percent of pore water, the chemical properties of the pore water, and percent of clay minerals. The attenuation rate normally decreases as both frequency and conductivity increase. Attenuation rate dictates how deep the radargram is.

The ability of GPR to identify subsurface layers or an object depends on (Davis and Annan 1989): (1) the frequency used; (2) the electrical permittivity contrasts among the subsurface materials; and (3) low attenuation rate. The pyroclastic deposits produced by phreatomagmatic eruptions are complex and vary in porosity, thickness, and grain size. The inhomogeneity in phreatomagmatic eruptions may greatly affect the ability of GPR surveys. In some exceptional cases, researchers have found that some basalt rich pyroclastic flows from a phreatomagmatic eruption attenuate much of the radar signal

within the first 1-2 m (Conyers and Connell, 2007). In most cases, a GPR survey can successfully perform on pyroclastic deposits because the pyroclastic deposits are typically thin (~10-100 m), electrically resistive, and likely to be located near the surface (Neal, 2004). The exceptional case in which GPR survey can perform on basaltic-andesitic ash flow deposits is because the material is very dried. Using 100 MHz GPR on dried basaltic-andesitic ash flow deposits, radar waves can penetrate up to 4-6 m (Conyers, 1995; Russell and Stasiuk, 1997). Listed here are the conditions of pyroclastic deposits that are GPR probable suggested by previous worker; in volcanic ash that has a permittivity that ranges between 4-7 F/m (Haggy et al., 2007), in the Bishop tuff (Grimm et al., 2007), Tumalo tuff (Haggy et al., 2007), and Tambora tuff (Abrams and Sigurdsson, 2007), where the attenuation rate of low frequency (50-150 MHz) radar signals varies between 10-50 F/m.

2.4 Physical Properties of Phreatomagmatic Eruption

2.4.1 Initial Gas Expansion Velocity

During a phreatomagmatic explosion, volcanic blocks are launched at an initial velocity equal to the maximum velocity of the expanding gas (Wilson, 1995). As their velocity decreases, volcanic blocks that were launched along with the gas are deposited when the gravitational force exceeds the drag force, which is dependent on atmospheric pressure and density. The important factors that determine the maximum gas expansion velocity, as well as the distribution of ejected volcanic blocks, include the mass ratio of water to magma (Wilson, 1995), the density of the mixture of fluid (water vapor) and pyroclastic particles (Sheridan, 1981), and atmospheric pressure (Fagents and Wilson

1995). Fagents and Wilson (1995) present a model for calculating the maximum velocity of volcanic blocks in a phreatomagmatic explosion from these parameters.

The relationship between gas expansion velocity (V_e) and radial distance from center of the eruption (R) is (Fagents and Wilson, 1995):

$$V_e = V_0 \left(\frac{R_0}{R}\right)^2 e^{-\frac{t}{\tau}} \qquad (3),$$

where V_0 is the initial gas expansion velocity of the gas i.e., the velocity at time zero (t_0) at radial distance R_0 from the center of the explosion; t is time; and τ is a time constant defined as the duration of the gas expansion phase (Fagents and Wilson, 1995). Equation (3) shows that the gas expansion velocity exponentially decreases as a function of time.

Assuming that the volcanic blocks were released from the vent at a velocity equal to the initial gas expansion velocity (V_0), both the gas and the volcanic blocks then decelerate (Equation (3)) as the gas plume propagates away from the vent and expands. If a volcanic block is dropped at a distance R from the vent, we can take the velocity V_e of the block at distance R to be an estimate of the volcanic block's velocity at impact. Quantitatively, V_0 is a direct result of water vapor that was released after the rupture of the volcanic vent. With known energy and the initial gas expansion velocity of an eruption, we can relate the size of volcanic blocks to the amount of groundwater that interacted with the magma source (Zimanowski et al., 1995). The time constant of the gas expansion phase also help us define the physical condition of a groundwater reservoir, for example the porosity and hydraulic conductivity of the aquifer (Fagents and Wilson, 1995). The long duration of gas expansion phase indicates that groundwater may be able to flow continuously to feed the eruption. A high flow rate of groundwater indicates a good hydraulic conductivity of the groundwater reservoir.

2.4.2 Block Size Distribution

Based on a semi-numerical model relating pyroclastic block sizes to their ejection velocities in Hawaiian and Plinian eruptions, Wilson (1999) show that clast size also exponentially decreases as a function of a decreasing expansion velocity (Figure 1). As volcanic gas and a volcanic block travel away from the vent, the gas is decelerated by frictions until it no longer has enough kinetic energy to carry the volcanic block; Once the kinetic energy is no longer strong enough to carry the weight of the blocks, the gravitational force overcomes aerodynamic forces and the volcanic block drops to the ground (Wilson and Bowell, 1971).

The largest volcanic blocks are found near the vent, where the gas velocity is the highest, and the smallest volcanic blocks are found further from the vent (Wilson, 1976). In the field, we can directly measure the sizes of dropped volcanic blocks (φ) and the distance of the blocks from the vent (R). With these two parameters we can calculate the velocity of the volcanic block at impact, which is also the velocity of the volcanic blocks at the time $V_e(R)$ it was dropped. Previous workers (e.g., Walker et al., 1971; Wilson and Bowell, 1971; Wilson 1999) have defined a relationship between volcanic block size and distance from the vents (Figure 1).

The gravity acceleration of a falling pyroclastic block ($g(y)$) is a function of its diameter (φ_i) and density (ρ_i); assuming that the block is a sphere shape. The aerodynamic force of the volcanic gas ($w(y)$) is controlled by the friction factor, C_d. The friction factor is a dimensionless quantity that is used to quantify the drag or resistance of a volcanic block in the plume of gas. Friction factor depends on the size and shape of a volcanic block. If a volcanic block is close to spherical, then the gas motion around a

block will be uniform and less turbulent than if the block is angular. In this case, C_d will have a value within about 30 percent of 0.7 (Wilson and Huang 1979). By balancing the gravitational force acting on the volcanic blocks and the drag force and kinetic energy exerted on it by the expanding gas, one can derive the impact velocity of the volcanic block (Walker, 1971):

$$V_e = \sqrt{[(4\varphi_i \rho_i g)/\,(3C_d \rho_g)]} \qquad (4),$$

where ρ_i is the density of volcanic blocks (3100 kg/m^3 for basalt); g is Earth's gravitational acceleration (9.81 m/s^2); C_d is an empirically-derived friction factor (~0.7; Wilson and Huang 1979); φ is volcanic block size (in m); and ρ_g is atmospheric density (4.7 ± 1.2 kg m^{-3}; Steiner and Babenko, 1978). We neglect lift forces in Equation (4) because the density of a pyroclastic block is much greater than that of air and the pyroclastic blocks are rarely observed to be spinning rapidly (Walker et al., 1971). The average Earth's atmospheric density at sea level is 1.225 kg m^{-3} at 15 °C. The atmospheric density at the time of Kilbourne Hole eruption is unknown but can be estimated using previous observations of other volcanoes (Patrick, 2007; Steiner and Babenko, 1978). If one can determine how the size of dropped volcanic blocks (φ) changes with distance from the explosion center (R), one can calculate the velocity of the blocks at the time they impacted using Equation (4). With that relationship, the initial gas expansion velocity can be determined using Equation (3).

2.4.3 Initial Gas Pressure

In a phreatomagmatic eruption, a sudden released of gas pressure and a vast expansion of volatile constituents occurred at the time of rupture (Fudali and Melson, 1970). Therefore, in addition to the initial velocity of the eruption, another important factor that determines the efficiency of the eruption is the initial pressure of volcanic vent prior the eruption. A number of investigators (Koelle, 1961; Fudali and Melson, 1970) have estimated the initial gas pressure within the vent ($P_{chamber}$) prior to an explosive eruption using the modified Bernoulli equation:

$$P_{chamber} = \frac{1}{2}\rho_d (V_0)^2 \qquad (5),$$

where ρ_d is the density of the material lying between the magma body and the surface.

2.4.4 Explosive energy

The explosive energy of an eruption can be expressed in terms of kinetic energy. The kinetic energy of an eruption is in the form of pyroclastic material moving away from the vent. At the moment of eruption, the potential energy associated with the accumulated gas pressure is converted to kinetic energy (E_k) (Zimanowski et al., 1995), which is quantified as:

$$E_k = \frac{1}{2}(M_f + M_w)V_0^2 \qquad (6),$$

where M_f is the mass of pyroclastic fragments and M_w is the mass of water. By knowing the kinetic energy, the maximum velocity of the gas (water vapor) and the pyroclastic fragments, and the mass of pyroclastic fragments, we can solve for the mass of water in the system.

2.4.5 Gas to Rock Mass Ratio

Several eruption models suggest various relationships and ratios between water gas to the solid fragment that could potentially produce large eruption. This gas to rock mass ratio in a phreatomagmatic eruption specifically refers to the weight of the water vapor to the weight of the rock fragment excavated and expelled from the vent during the explosion. Fagents and Wilson (1993) generated a model to define percent of gas to solid rock fragments in relation to the initial gas expansion velocity and the initial pressure. Self et al (1993) documented cloud gas of several eruptions. Self et al (1979) suggested maximum 10-30% of gas to rock mass ratio while Fagents and Wilson (1993) suggested only 1-5% of gas to rock mass ratio could resulting in large-scale explosion. How magma would interact with such high percentage of water in a very short period of time in the case of Self et al (1979) is still uncertain. Self et al (1979) explicated the long cylindrical geometry of the magma vent, maximized the chances of groundwater being involved in the eruption. Where Fagents and Wilson (1993) argued that the initial pressure of the eruption is limited by the rock strength and the maximum amount of water vapor that can be contained in the rock formation is limited by its porosity. Hence It is likely that a high gas to rock mass ratio in a large-scale explosion is instead associated to the large size of the magma region. In this research we utilized the eruption model of Fagents and Wilson (1993) to derive the gas to rock mass ratio and the amount of groundwater at Kilbourne Hole during the time of eruption. Fagents and Wilson (1993)'s explosion model provides a mathematic relationship between various initial velocities, initial pressure, and the ratio of gas to rock fragments that were released from the eruption.

Fagents and Wilson (1993)'s eruption model of Vulcanian eruption suggested a volatile rich (1-10 wt%) mixture of magma, vaporized groundwater and exsolved volatiles, must be trapped at high pressure ranges between 1-100 bars in order to initiate the initial gas expansion velocities at the time of rupture to be between 100-400 ms^{-1} (Fudali and Melson, 1970; Self, 1979; Fagents and Wilson, 1993). The weight percent between the mass of vaporizing gas to an initial mass flux of rock fragments that were released at rupture is gas to rock fragments mass ratio (n). High initial gas expansion velocity and high initial pressure at the time of rupture indicates high gas to rock fragments mass ratio. Vice versa, the low initial gas expansion velocity and low initial pressure indicates low gas to rock fragments mass ratio (n).

The sizes of the volcanic blocks and the internal structure of Kilbourne Hole are the keys to understanding how explosive Kilbourne was at the time of eruption. We can derive the initial velocity of the volcanic blocks by knowing the size of the volcanic blocks and its location from the vent. We can also derive the initial pressure within the vent by knowing the initial velocity and the density of the cap rock material. The derived initial pressure and the initial velocity can be used to estimate the weight ratio of water vapor to the weight of rock fragments that were released from the eruption (Self et al., 1979; Fagents and Wilson, 1993). Hence, we can estimate the weight of liquid water in the ancient groundwater reservoir.

3. Study Area

Kilbourne Hole is a well-known phreatomagmatic volcanic crater located in Southern Doña Ana County, New Mexico (Figure 2). This maar crater is a 2-km wide depression, and it is about 200-m deep (Reiche, 1940). The area around Kilbourne Hole is covered with 50-150 m of pyroclastic deposits. Underneath this volcanic ash are the Aden and Afton basalt flow lava flows. The Kilbourne Hole eruption occurred during the mid-Pleistocene (0.02-0.1 Ma; Seager, 1984). Seager (1984) and Lorenz (1973) suggest that the excavation of Kilbourne Hole was caused by catastrophic subsidence, similar to caldera collapse, following phreatomagmatic explosive activity.

Kilbourne Hole is located along the southwest margin of the Rio Grande rift. The Rio Grande rift, and the series of basins related to it, is a major tectonic feature of the North American continent that extends from Colorado through New Mexico, and into northern Chihuahua, Mexico, covering a distance of about 950 km (Ramberg et al., 1978; Keller et al., 1990). The extension that formed the Rio Grande rift, and the associated volcanism, began about 30 million years ago (Ingersoll, 2001) and still continues today (Keller et al., 1990). Volcanic activity can be found throughout the Rio Grande rift (Lipman, 1969). The volcanic activity along the Rio Grande rift varies from alkalic to tholeiitic basaltic volcanism activity. The changes in types of volcanism composition indicate the magma source of volcanic activity within the Rio Grande Rift is derived from various depths. Tholeiitic basalts originate at shallower depths than alkalic basalts (Lipman, 1969), suggesting the movement within the vent. During the Pliocene to Quaternary, volcanic activity in the Rio Grande Rift mostly erupted alkali-olivine basalt and, in some localities, tholeiitic basalts (Keller et al., 1990).

The Kilbourne Hole eruption occurred during the Pliocene to Quaternary Rio Grande rift phase (5 Ma to present). Prior to the Kilbourne Hole eruption, the area was already covered with at a series of volcanic flows that erupted from Aden and Afton craters (Hoffer, 1972; Seager, 1984). Below the Afton-Aden basalt flows is the Late Quaternary (2-3 Ma) Santa Fe group (Figure 2), a 1.5-2 km thick package of fluvial sediments deposited by the ancestral Rio Grande River (Seager, 1984). There are two parts of the Santa Fe group. The younger unit is the Camp Rice Formation, which contains fluvial and piedmont sediments (Lorenz, 1986). The older unit is the Fort Hancock formation, which contains alluvial sediments (Hawley, 1975).

The Kilbourne Hole eruption is the most recent event of in the Pliocene-Quaternary rifting period (Hoffer, 1972). The Kilbouren Hole eruption excavated the Santa Fe group and the overlying Afton-Aden basalt flows. Both pre-eruptive units can be seen exposed inside Kilbourne Hole. The Kilbourne Hole explosion deposited 50-150 m of air-fall and pyroclastic surge deposits around the crater rim (Lorenz, 1986). Pieces of alkali olivine can be found within the pyroclastic deposits, indicating that there is basaltic intrusion located underneath Kilbourne Hole (Hoffer, 1972; Hawley, 1975). The pyroclastic deposits can be traced 800-1000 m radially away from the modern crater rim (Seager, 1987). There are two sets of pyroclastic layers: one that deposited around the crater rim, and one that has collapsed into the crater (Figure 3). The dips of both sets of pyroclastic strata range from 8° to 35° (Seager, 1987). After the Kilbourne Hole eruption, aeolian and fluvial sediments were deposited throughout the area, including the interior of Kilboune hole, and these deposits mantle all of the older units (Figure 3).

4. Methodology

4.1 GPR Survey Design for Kilbourne Hole

In November 2014 we performed several initial GPR experiments at Kilbourne Hole using a 250-MHz Noggins Plus GPR unit to determine the radar wave velocity, sampling frequencies, gain, and filtering methods that would provide the best results. The GPR surveys to map the size distribution of volcanic block at Kilbourne Hole is possible because of the high electrical permittivity contrast between mafic volcanic blocks and the pyroclastic deposit. We also evaluated the electrical properties of the geologic materials at the survey sites in order to properly design the detailed GPR surveys that followed. We used these parameters in the processing of data from our GPR surveys to locate and determine the sizes of buried volcanic blocks.

Our approach to estimate the radar wave velocity of the pyroclastic deposit at Kilbourne Hole was to use a 250-MHz Noggins Plus GPR unit to acquire several GPR profiles over a 10-mm diameter and 30-cm long iron metal rod buried to a known depth of 0.45 m and then calculate the radar wave velocity using Equation (2). The rod was buried to a known depth of 0.45 m in the pyroclastic material at Kilbourne Hole. Because the rod has a large electrical permittivity (e > 100 F/m) and a high attenuation ratio (β > 1000 dB/m), radar waves are poorly transmitted though it and are instead directly reflected back to the GPR receiver. This produces a hyperbolic reflector in the resulting radargram (Figure 4). The apex of the hyperbolic reflector is located at the bottom of the buried metal rod. Using a modified exponential curve fitting routine (Milsom, 2003) in the *Ekko Pulse* software suite, we estimate the wave velocity in the pyroclastic deposits above the metal rod at Kilbourne Hole to be 0.13 m ns^{-1}.

This data for a known target also allowed us to determine the permittivity of the pyroclastic material at Kilbourne Hole. Using Equation (1), we calculate the electrical permittivity of the pyroclastic deposits at Kilbourne Hole to be ~2.2 F/m. This relatively low permittivity means that most of the GPR signal will not be propagated into the media, most signals will instead be scattered and some small signal attenuation may occur.

To make sure that the radar waves can reach the desired survey depth of more than 1m, we also must know the attenuation constant of the pyroclastic deposits. Empirically determined signal attenuation values were provided by previous workers (i.e., Ulaby et al., 1996; Davis and Annan, 1989; Milsom, 2003). For silty materials with permittivity of ~2.2 F/m, the attenuation rate (β) is between 100-300 dB/m. We did not perform a laboratory study to measure the attenuation rate of volcanic ash at Kilbourne Hole, but, by applying an AGC of 300 dB to the radargrams, we were able to regain the deeper part of the radargrams that previously before the data processing were too weak for photointerpretation. Based on the electrical properties of the geological material at Kilbourne Hole, the GPR receiver was set to sample at 1-ns intervals during data collection and data processing to retrieve the best quality GPR image. Using the Shannon-Nyquist theorem, we estimate the sampling frequency to be ~1000 MHz.

All GPR data was imported into and processed with the *Ekko Pulse* software suite to improve the quality of the resulting GPR radargram. The processing steps were: (1) temporal filtering (de-wowing) to increase contrast and sharpness; (2) stacking the returned signal to remove very low-frequency components; and (3) AGC (automatic gain control) at 300 dB to compensate for attenuation of the radar signal and to gain visibility

of the weak radargram trace. We stacked the arrival radar signal four times to eliminate background noise while maintaining the best image quality. The penetration depth of the 250-MHz instrument at Kilbourne Hole seen in the radargram was between ~2.54-3.58 m based on our field calculation using two way travel time of 0.13 ns/m. Our processed radargrams provide high-resolution images that allow us to identify and measure the sag features that are preserved in the tephra units at Kilbourne Hole.

4.2 Short GPR Surveys and Radargram Calibration

To learn how to recognize volcanic blocks and associated sags on our processed GPR images, we made GPR measurements over outcrops with exposed volcanic blocks and associated sags along 29 short (<10-m long) transects on the rim of Kilbourne Hole (Figure 5). These short profiles were collected in January 2013 and in January 2014 using a 250-MHz Noggins Plus GPR unit and the acquisition parameters and data processing workflow described in Section 4.1. The resulting radargrams were displayed with 2x vertical exaggeration at a scale of 1:39 and were manually photointerpreted to trace the locations of both sags and volcanic blocks (Figure 3).

By comparing the exposed outcrops to their GPR profiles, we found two prominent types of reflectors in the resulting radargrams (Figure 3). The first type (Type 1) includes strong, continuous, smooth, undulating reflectors that correspond to the horizontal layers in the pyroclastic flow deposits. Basaltic volcanic blocks appear as the second type of reflector (Type 2), which are very dim and weak. The basaltic volcanic blocks appear this way because they have higher permittivity due to their high iron and magnesium content (Russell et al., 2013) and, as a result, they attenuate the GPR signal.

These two distinctive types of reflectors allow us to discriminate volcanic blocks from sags on GPR profiles. Knowing what they look like we can measure the apparent widths of buried volcanic blocks and sags directly from GPR radargrams.

The remaining question, however, is the relationship between the apparent widths of these features on GPR radargrams and their actual widths. To answer this question, we compared the widths of exposed volcanic sags and blocks in the field to the apparent widths of the same features as observed on the GPR radargrams obtained from our short profiles. Because volcanic sags are wider at the top than at the bottom, an objective and consistent definition for width was needed. The width is defined as the length of the imaginary line drawn through the middle part of the sag between the top and the bottom of the sag and through the center of the volcanic block (Figure 4a). Using this definition, a calibrated screen ruler application (*Ruler 1.0* for Windows) was used to measure the apparent width of the sags identified in the short transect radargrams. The field measurements of the widths of the volcanic sags and blocks were obtained with a measuring tape using the same width definition used for measuring sags on the radargrams (Figure 4b). The uncertainty of these measurements both in the field and on the radargrams is 0.05 cm, which is the margin of error for the ruler. Other possible sources of error include human error and subjectivity when choosing points of measurement.

Because the Type 2 reflectors associated with volcanic blocks are difficult to interpret, we are unable to reliably identify blocks in the GPR radargrams and are therefore unable to accurately determine their widths using the GPR radargrams. However, the apparent widths of the Type 1 reflectors associated with sags can be

accurately measured on the radargrams and related to their actual widths as measured in the field. Based on the assumption (Walker and Croasdale, 1971) that the size of a sag is proportional to the size of the volcanic block that created it, we establish an empirical relationship between the widths of sags and the widths of volcanic blocks as they appear in the outcrop. With this intermediate step, we can then relate the widths of sags measured in GPR radargrams to the actual widths of the volcanic blocks that created them.

4.3 Long GPR Surveys at Kilboune Hole

In January 2012, January 2013, and January 2014, we collected GPR data along 6 long transects extending radially away from the rim of Kilbourne Hole in each cardinal direction (Figure 5). The transects varied in length from 250 m to 1,000 m, depending on accessibility, each extending a distance sufficient to include the entire area covered by the Kilbourne Hole pyroclastic deposits. We used the same 250-MHz Noggins Plus GPR equipment and the same GPR instrument parameters and processing steps described in Section 4.1. The purpose of GPR surveys on these long transects was to collect the sizes distribution of the volcanic blocks and sags that were buried within the pyroclastic deposits around the rim of Kilbourne Hole crater (Figure 6). The length of these long surveys line is long enough to reveal the changing trend in sizes of the volcanic blocks and sags.

4.4 Velocity at Impact of Volcanic Blocks

We calculate the impact velocity of a volcanic block from its size and location using Equation (4). The atmospheric density at the time of Kilbourne Hole eruption is unknown. We do know that the average Earth's atmospheric density at sea level is 1.225 kg/m^3 at 15 °C. However, during the Kilbourne Hole eruption, the atmosphere was mixed with the volcanic gas plume. As a result, it was hotter than the ambient atmosphere and was probably filled with volcanic particles. Steiner and Babenko (1978) observed that the atmospheric density of the volcanic gas in a Strombolian eruption can be as much as 4.7 kg/m^3, and Patrick (2007) modeled the density of the volcanic gas in a Plinian eruption to be >3.5 kg/m^3. Based on this, we chose a density of 4.7±1.2 kg m^{-3} to represent the atmospheric density at the time of Kilbourne Hole eruption. The impact velocity is then used to calculate the initial velocity when the gas and volcanic blocks were first released from the vent. The workflow of how to calculate the initial velocity of the gas and volcanic blocks from its impact velocity is shown in the following paragraph.

4.5 Initial Pressures of the Volcanic Vent

In the case of Kilbourne Hole, the initial gas pressure (P) was trapped under the weight of cap rocks before the rupture. The density of cap rocks is varied; we used a weighted average density of both Aden and Afton basalt (3,100 $kg.m^{-3}$) and the Camp Rice formation (2,160 $kg.m^{-3}$). At Kilbourne Hole ρ_d used in the initial pressure estimate (Equation (6)) is 2,164.7 $kg.m^{-3}$.

4.6 Initial Velocity of the Eruption Analysis

In addition to the size of the blocks, our GPR survey provides the lateral distance from the vent for each volcanic block we found. In order to apply Fagents and Wilson (1995)'s velocity model to retrieve the initial gas expansion velocity (Equation (3)), we convert lateral distance from the crater rim (in Cartesian coordinates (x, y)) into radial distance from the vent (in polar coordinates (r, θ)) (Figure 7). Assuming that the volcanic block is denser than the gas plume and was ejected following ballistic trajectories, the coordinate transformation from Cartesian coordinates to polar is given by:

$$r = \frac{\cos\theta}{x} \qquad (7),$$

where x is lateral distance between the volcanic block and crater rim, and r is a radial distance between the volcanic block and the vent. The location of the vent was estimated using a magnetic anomaly map of Kilbourne Hole (Rhodes and Hurtado, 2012; see Chapter 2). The vent is the location where an eruption was originated. The vent is later filled by fragments of the diatreme filling including highly brecciated pre-eruptive rocks, volcanic origin rocks, and post eruptive material. The vent of Kilbourne Hole is not seen on the surface, but the can be seen on the magnetic and gravity anomaly map of Kilbourne hole due to its unique magnetic susceptibility and density properties of vent filling material. We define that the present location of Kilbourne Hole's vent is where the body of diatreme filling material were buried near the center of Kilbourne Hole. The extensions of the diatreme filling normally are from the pre-eruption surfaces to the top of the volcanic dikes. Our magnetic model provides a best estimate depth to the top of the dikes (which is also the thickness of the diatreme filling body) to be 920 ± 120 m and the radius of the vent to be (349.5 ± 40 m) (Rhodes and Hurtado, 2012). In the radial

distance calculation in Equation (7) the top of the volcanic dikes at the depth of 920 ± 120 km is considered to be the center point of ejection or the beginning of the vent of the volcano. The radius of the vent is expected to be smaller than the radius of present day crater because of erosion; the radius of the present day crater is larger than radius of the vent at the time of eruption. We draw the best-fit circle that inscribes the present day crater rim (Figure 7) and use the radius of that circle as our estimate for the radius of the vent at the time of eruption. We use this radius to convert lateral distance from the crater rim to dropping locations of the volcanic blocks to radial distance from the center of the vent to dropping locations of the volcanic blocks (Figure 7 and Equation (7)).

A MATLAB code (Appendix A) was written to plot impact velocity versus radial distance and to fit the explosion model of Fagents and Wilson (1995) to the data using a least-squares regression (York, 1968; York, 2004). To do this, we first linearize Equation (3) to yield:

$$\log V_e = 2\log V_0 \frac{R_0}{R} - \frac{t}{\tau} \qquad (8).$$

If we assume that the ejected gas and pyroclastic material both have velocity V_0 at a distance $R = R_0$, we can write:

$$\log V_e = 2\log V_0 - \frac{t}{\tau} \qquad (9).$$

Given that: $Y = a + bX$ (10).

Then we can write: $Y = logV_e$ (11),

$$X = t = \frac{R}{v_e} \qquad (12)$$

$$a = 2logV_o \qquad (13)$$

$$b = -\frac{1}{\tau} \qquad (14)$$

By replacing the calculated flight time (t) (using Equation (12)) and the impact velocity of the volcanic block into Equation (10), we can determine V_0 and τ by from the linear regression coefficients *a* and *b* using Equation (13) and (14).

4.7 Gas to Rock Mass Ratio

To determine the gas-to-rock mass ratio of Kilbourne Hole eruption we plotted our derived initial velocity of the volcanic blocks (V_0) and the initial pressure (P) of the vent on Fagents and Wilson (1993) 's eruption model. The major application of this model is for the prediction of the amount of water vapor (gas) that was released considering the initial conditions in the vent (Initial pressure, initial velocity of the volcanic blocks). This eruption model only described the simplest behavior of the eruption ignoring the presence of wind shear or the formation of a convection cloud above the vent. This model can best explain the behavior of the larger size and more dense ejected material (e.g., millimeters size particles) and large volcanic blocks, which are demonstrably less affected by the atmosphere. This model can only provide rough result for smaller and less dense ejected material or the material that are more vulnerable to atmospheric motion inside the convection cloud.

According to this Fagents and Wilson (1993)'s eruption model, in transient explosions where there is some meteoric water is in addition to magmatic volatiles, gas to rock mass ratio of 0.01 to 0.1 (1 to 10 percent) is commonly involved in order to generate initial velocities of large volcanic blocks span values from a few tens of $m.s^{-1}$ to 400 $m.s^{-1}$. This amount of gas-to-rock mass ratio is also required the initial gas pressures inside

the vent to be significantly less than 40 MPa and to be consistent with the strengths of the cap rocks under which pressure accumulation occurs (Fudali and Melson, 1972).

The gas-to-rock mass ratio allows us to calculate the amount of gas (predominantly water vapor) in the system at the time of the eruption. To do this, we must estimate the mass of the rock fragments that may be released from the vent of Kilbourne Hole at the time of rupture. Assuming that all the cap rock was later removed and excavated from the crater as rock fragments, we can estimate that the mass of rock fragments equals to the mass of the cap rock. By cross multiplying the mass of rock fragments to the gas-to-rock mass ratio, we then can resolve for the mass of gas, hence groundwater that fed the Kilbourne Hole eruption.

4.8 Propagation of Uncertainties

All measurement of the width of the volcanic sags and blocks at Kilbourne Hole contains uncertainties from both the GPR instrument and from measurements apparatus. The entire model derived quantities such as locations, depths, width and length of volcanic vent and dikes used in our calculation contains uncertainty from both gravity and magnetic surveys at Kilbourne Hole. Because our final results (initial velocity, initial pressure, mass of water) are depends on these those mentioned quantities, we must propagate the uncertainties from those quantities into our final results (Ku, 1966; Taylor, 1997). We follow a standard rule of uncertainties propagation by Ku (1966) and Taylor (1997). The rules of error propagation used in this research are under an assumption that all quantities that contain errors are uncorrelated and random.

5. Results

Using the 250 MHz noggins GPR unit, we are able to image sags, volcanic blocks, and crossbedding within the pyroclastic deposit at Kilbourne Hole. The retrieved GPR images provide a great resolution of objects as small as ~25 cm and bedding as thin as ~10-20 cm. Our GPR surveys at Kilbourne Hole achieved penetration depths into the pyroclastic deposit of 2.45 m to 3.78 m at most survey localities. The radar propagation velocity in the pyroclastic deposits at Kilbourne Hole is ~0.11-0.13 m/ns. We found that the radar signal in the pyroclastic deposits at Kilbourne Hole dissipated quickly after a certain depth (~ 3-4 m.), which may be due the development of caliche-rich B soil horizons, which are common in arid environments (Tatum and Francke, 2012).

5.1 Relationship Between the Widths of Volcanic Sags Measured with GPR and Measured in the Field

We obtained 29 measurements of exposed volcanic sags and associated blocks from the short GPR surveys. We then plotted the volcanic sag width as measured from the radargrams ($\varphi_{sag,GPR}$) versus the actual width of the sag as measured in the field ($\varphi_{sag,field}$). Figure 8 shows a linear regression ($r^2 = 0.91$) through this data:

$$\varphi_{sag,GPR} = 0.9185\varphi_{sag,field} + 5.8529 \quad (15).$$

We used this relationship to correct our GPR measurements result to be as close as our field measurement results (Appendix A).

5.2 Relationship Between the Actual Widths of Volcanic Sags and Associated Volcanic Blocks

At the field locations of volcanic blocks and sags we performed 29 width measurements of exposed volcanic sags and associated blocks. We then plotted the actual width of the volcanic sags ($\varphi_{sag,field}$) versus the actual width of the volcanic blocks ($\varphi_{block,field}$). The result of this measurement provided statistical evidence that the width of the volcanic sags is highly depending on the width of the volcanic blocks. Figure 9 shows a linear regression (r^2 = 0.54) through this data:

$$\varphi_{sag,GPR} = 0.9185\varphi_{sag,field} + 5.8529 \quad (16).$$

5.3 Relationship Between the GPR Widths of Volcanic Sags and Associated Volcanic Blocks

Because the volcanic blocks at Kilbourne Hole are mostly ultramafic basalt, their high iron contents prevent our GPR radargrams from yielding a clear and bright reflector of volcanic blocks. By plotting the GPR width measurements of volcanic sags to the field width measurement of the volcanic blocks, we are able to establish a direct relationship that allow us to relate the width of volcanic sags to the width of the volcanic blocks that created the volcanic sags.

The resulting relationship between the GPR width of volcanic sags ($\varphi_{sag,GPR}$) measured from GPR radargrams and the actual width of volcanic blocks as measured in the field ($\varphi_{sag,field}$) shows a linear regression (r^2 = 0.43) (Figure10) as describe in the following equation:

$$\varphi_{blocks} = 0.1604\varphi_{sags\_GPR} + 22.273 \quad (17).$$

5.4 Volcanic Block Size Distributions From Long GPR Transects at Kilbourne Hole

We collected a total of six long GPR surveys lines extended approximately ~ 600-1000 m long radially from the crater rim. We are able to detect and visualize volcanic sag features along those surveys ling. The length of the long survey line provides us the opportunity to recognize the distribution trend of the volcanic sags size. On the processed GPR radargrams, we measured the width of the volcanic sags found buried along the survey lines. We calibrated the volcanic sag width measurements from the GPR to its filed width using Equation (16). We converted the calibrated width of the volcanic sags into the width of the volcanic blocks that created the sags using Equation (16). Using the width of the volcanic blocks obtained from Equation (17), we calculated the impact velocity of the volcanic blocks at the dropping location using Equation (4). The lateral distance of the volcanic blocks and sags locations from the crater rim were also converted into its radial distance from the center of the vent using Equation (7). The volcanic blocks width and calculated radial distance are shown in Table 2 and Appendix A. We then plotted the result of volcanic blocks widths to its radial locations (Figure 10) and we then applied the Fagents and Wilson (1995) eruption velocity model to our results (Equation (3)). Figure 10 shows an example using data plot from long survey line 3. The data plots from other five long survey lines are included in Appendix B. Figure 11 shows calculated impact velocity of the volcanic blocks found along the survey line 3 plotted against radial distance from the crater rim. Figure 11 shows a negative exponential trend, which indicates that the gas expansion velocity decreases as the distance from the center of the eruption increases.

5.5 Initial Gas Expansion Velocity and Initial Pressure of the Vent

The York's least square regression between the result of volcanic blocks widths measurement and radial distance of the volcanic blocks and the Fagents and Wilson (1995) eruption velocity model (Figure 12), yields us two results: the initial gas expansion velocity (*Vo*) and the time constant of the gas expansion phase (*t*). The initial gas expansion velocity (*Vo*) and the time constant of the gas expansion phase (*t*) results retrieved from each of the six long GPR transects are listed in Table 3. Each result for *Vo* and for *t* are including their propagated uncertainties from each measurements and initial input data. We average results from all six long GPR transects to yield an average *Vo* of 123 ± 9 m s^{-1}; and an average *t* of 92 ± 11 s. With the now known initial velocity of the gas expansion, we can calculate the initial pressure inside the orifice using the modified Bernoulli equation (Equation (6)). The initial pressure inside of the vent prior to the eruption was 163 ± 9 bar.

5.6 Gas-to-Rock Mass Ratio and Groundwater in Kilbourne Hole Eruption

We applied our initial velocity of the volcanic blocks and initial pressure of the vent results to the theoretical models of phreatomagmatic explosions by Fagents and Wilson (1993) to determine the gas-to-rock mass ratio of Kilbourne Hole eruption (Figure 12). By plotting our results to the model, we predict that the gas (m_g)-to-rock (m_s) mass ratio during the Kilbourne Hole eruption was 1 – 2 % (0.01-0.02)(Figure 13).

Using this gas-to-rock mass ratio and the estimated masses of ejected rock fragments from the vent of Kilbourne Hole at the time of rupture, we were able to calculate the amount of gas (predominantly water vapor) in the system at the time of the

eruption. By assuming that the mass of rock fragments equals to the mass of the cap rock, we estimated that the mass of rock fragments release from the vent of Kilbourne Hole at the time of eruption contains ~15 ± 5 m thick of Aden and Afton basalt (Seager, 1984) and approximately 920 ± 120 m of the Camp Rice formation (Rhodes and Hurtado, 2012). The thickness of Camp Rice formation material that may be ejected as rock fragments is considered to be equivalent to the thickness of Camp Rice formation from the pre-eruptive surfaces to the top of the upper most dike appeared on our gravity and magnetic model of Kilbourne Hole (Rhodes and Hurtado, 2012). Also from our gravity and magnetic model of Kilbourne Hole (Rhodes and Hurtado, 2012), we estimated the radius of the cap rock (R_d) to be ~349.8 ± 40 m. The volume of the cap rock was calculated assuming a cylindrical shape and an average weighted density of the basalt and the Camp Rice formation of 2,175.32 kg m^{-3} using this equation:

$$vol = \pi R_d^2 h \qquad (18).$$

This gives a volume of 3.54 ± 0.46 x 10^8 m^3 and a mass of 7.69 ± 1.00 x 10^{11} kg cap rock. For a gas-to-rock mass ratio of 0.01, this yields 7.7 ± 1.0 x 10^9 kg of water vapor. For a gas-to-rock mass ratio of 0.02, this yields 14.1 ± 2.0 x 10^9 kg of water vapor

6. Discussion

6.1 Assessment of Radar Properties Kilbourne Hole and Mars-Analog Phreatomagmatic terrains

Our GPR data of Kilbourne Hole suggest GPR method is a suitable for subsurface imaging on pyroclastic flow deposit and probing basaltic volcanic blocks. The geological setting of Kilbourne Hole locating in Chihuahua desert also yields similar site conditions (e.g., high aridity) to Mars Home plate. We found that the permittivity of the pyroclastic deposits at Kilbourne Hole is ~2.2 F/m with an attenuation constant of ~100-300 dB. Picardi et al (2004) using a 2 MHz-SHARAD data and found that an average electrical permittivity of the Martian regolith is ~6 F/m with an attenuation constant as low as ~30-50 dB. Vaucher et al. (2009) tested two volcanic ash units and a basaltic lava flow in Elysium Planitia using data from SHARAD. The electrical permittivity of the basaltic lava flow is ~ 8.8 ± 1.0. The Martian subsurface has higher electrical permittivity and lower attenuation rate than at Kilbourne Hole. Based on these estimates, the Martian subsurface is suitable for using GPR method. It is likely to be able to obtain better radargrams and deep radar penetration ranges on Mars than at Kilbourne Hole using similar equipment and survey design. Our GPR result at Kilbourne Hole agrees with Stillman and Olhoeft (2006)'s suggestion that the lack of liquid water and its associated low conductivity in the Martian subsurface should result in a good GPR environment. Even though Heggy et al. (2006) and Olhoeft (2003) pointed out that the iron oxide rich Martian subsurface could attenuate the GPR signal propagation, we do convince that that high electrical permittivity of Mars surfaces (~3 times higher than Kilbourne Hole

surface) should overcome the radar attenuation due to dielectric and magnetic losses from iron oxide rich subsurface materials.

6.2 Assessment of GPR Image Quality at Kilbourne Hole and Mars-Analog Phreatomagmatic terrains

With our GPR radargrams, we were able to image three distinct volcanic features: (1) sags; (2) volcanic blocks; and (3) cross-bedding in pyroclastic deposits. The image of volcanic blocks, however, is dimmed and not as bright as other image's reflectors. Using 250 MHz frequency GPR unit, we achieved 2.54-3.68 m penetration depth and 0.25 m resolution. We are able to image sags as small as 25 cm wide and pyroclastic layers as thin as 25 cm. For comparison, in Figure 14 we show volcanic sags and volcanic blocks features at Kilbourne Hole in comparison to Home Plate. It is obvious that Martian volcanic blocks and volcanic sags are identical to the same features at Kilbourne Hole but may be smaller in sizes. One volcanic block identified at Home Plate on Mars is 3.8 cm wide (Lewis et al., 2008) (Figure 14). Our results also demonstrate a used of medium frequency GPR in mapping mafic volcanic blocks, and alkaline pyroclastic deposit that contain significant amount of calcium rich top soil. We suggest that 250 MHz is the most suitable frequency to perform a GPR survey on Mars Home Plate considering the geological setting and the size of volcanic bocks and sags we imaged. We may need to consider a higher frequency GPR on Mars in order to increase the survey resolution so that we can detect smaller sizes volcanic blocks (Lewis et al., 2008). Therefore we suggest that a similar GPR survey could be conducted on either a robotic or human exploration mission to study features such as Home Plate on Mars.

6.3 Kilbourne Hole Eruption

Our model velocity model indicates that after the rupture of the cap rocks, rock fragments and gas were expanded from the vent at the initial velocity of ~113-132 m s^{-1}. These initial velocities of the volcanic blocks are consistent with observations of historical eruptions (e.g., Iguchi et al., 1983; Ishihara, 1985, 1990; Morrissey and Mastin, 2000; Parfitt and Wilson, 2008) and empirical calculations of the dispersal of large clasts by Fagents (1993) and Fagents and Wilson (1993). Observed at Sakurajima volcano in Japan in 1982-1987, the initial velocities of volcanic blocks were estimated to be 110-240 m s^{-1} (Iguchi et al., 1983; Ishihara, 1985, 1990). Observed at Shinmoedake volcano in Kyushu, Japan on February 1, 2011**,** the initial velocity of volcanic blocks was 240-290 m s^{-1} (Maeno et al., 2013). Our calculation based on estimated strength and thickness of cap rock indicates that the initial pressure of the vent before the rupture of Kilbourne Hole was 163 ± 9 bar and that expansion event of the rupture lasted 92 ± 11 s after initiation. Observed during its two-day eruption event, the maximum time duration of the gas fexpansion at Usu volcano was 97.5 s during these two days (Yokoo, 2002).

6.4 Paleohydrological Interpretation of Kilbourne Hole

Following the eruption model proposed by Fagents and Wilson (1993), we plotted the range of obtained initial velocity of the volcanic blocks and the initial pressure of the vent on the model (Figure 15). Fagents and Wilson (1993)'s eruption model indicates that Kilbourne Hole eruption was supplied by the gas-to-rock mass ratio at 0.01-0.02 (1-2%). These results are adjacent to the other observations of recent phreatomagmatic volcanoes.

The observation at Ngauruhoe where at the time of its eruption has the initial pressures of 1 to l0 MPa and the initial velocities of the ejected volcanic blocks were 220 to 250 m s^{-1}. The eruption was estimated to have gas-to-rock mass ratio of 2-6% and have sent a 0.8 m volcanic blocks to the distance as far as 2.5 km. Another observation from the Ukinrek Maars eruption, were the initial pressure and the initial velocity of the volcanic blocks that are larger than 2 m in size at the time of eruption are 0.1 to 5 MPa and 82 to 85 m s^{-1}**,** yield gas-to-rock mass ratio of 1-5%.

Our results are still problematic, however, because the presence of tuff ring and abundant accretion lapilli in pyroclastic deposits at Kilbourne Hole suggests a wet eruption. In general, the porosity of consolidated sand, which is a typical aquifer material in Rio Grande basin, is 22% (Crilley et al., 2013). Assuming that the Kilbourne Hole groundwater reservoir was fully saturated at the time of the eruption, the explanation for this low percent of water we can suggest is that our estimated dry eruption at Kilbourne Hole is not representative of the entire eruption, but only the last stage of the eruption, where the previous eruption had depleted the majority of the water resources.

Additional explanation is that Fagents and Wilson (1993)‘s eruption model provided usually much smaller gas to rock mass ratio than values estimated by previous workers (Fudali and mason, 1972; Self et al., 1979; Wohletz, 1986). Fagents and Wilson (1993) discussed the limitation of their model that it can best explain the eruption phenomenon of coarse grain ejecta (>1 mm) or volcanic blocks because their velocity model did not considering the turbulent movement inside the eruption gas plume. Hence the model result on large volcanic block is more reliable for it has sufficient mass to not be effected by the turbulent or side way movement of the gas cloud. However, Wood

(1995) pointed out that the result on large volcanic blocks may not be more relaible because when large volcanic blocks are ballistic dispersed with other rock fragments, the heat cannot be transferred from the volcanic blocks to the gas in the timescale of an explosion (Woods, 1995). Therefor large size volcanic blocks do not remain in thermal equilibrium with the gas, thus leading to significantly lower velocities and temperatures than predicted by an equilibrium model (Wood, 1995).

It must be noted that the penetration depth of our GPR radar is ~2.54-3.58 m and that the volcanic blocks we detected are located at depths shallower than that. Our survey may have missed larger volcanic blocks (~> 2m diameter) that may have been deposited deeper in the pyroclastic deposits. Those deeper volcanic blocks may represent earlier phases of the eruption. It is possible that by the last stage of the eruption, the water source may have already been depleted and the magma source may have lost a substantial amount of internal heat energy. Both of these would lower the eruption efficiency in a manner consistent with our results while also explaining why the geology of the pyroclastic deposits at Kilbourne Hole is consistent with an overall wet eruption.

7. Conclusion

The phreatomagmatic activities suggested that ancient Mars was warm, wet, and dynamically active. Understanding past phreatomagmatic activity on Mars can potentially provide us with information about the ancient Martian hydrosphere. Not only does a phreatomagmatic volcano confirm the existence of an external source of water, but it also provides information of how Martian groundwater, surface water, and magmatic sources interacted. We conducted a geophysical survey at Kilbourne Hole, a well-known phreatomagmatic volcano in New Mexico, using GPR to demonstrate the use phreatomagmatic volcanic features as paleohydrological proxies. Our GPR surveys revealed buried volcanic sags and volcanic blocks around Kilbourne Hole. By measuring the size distribution of volcanic blocks as a function of distance from Kilbourne Hole, we determined the initial gas expansion velocity during the eruption to be 123 ± 9 m s^{-1} and the time duration of the entire gas expansion phase to be of 92 ± 11 s. The initial pressure prior to the eruption was calculated to be 163 ± 9 bars. The length of time duration of the gas expansion phase is a good indicator about the groundwater reservoir that fed the eruption. The better the groundwater hydraulic flow, the longer the steam is continuing to release. The initial pressure of the eruption is an implication to the depth of eruption center, depth of groundwater level, and the type of groundwater reservoir at the time of eruption. In the case of a phreatomagmatic eruption like Kilbourne Hole, the eruption is originated at the contact zone between magma and groundwater reservoir. Therefor we can consider that the depth of eruption is roughly the paleo-groundwater level. In time duration of gas expansion at Kilbourne Hole may not be

a good representative of the entire eruption because we can only detect the velocity of volcanic blocks that dropped at the shallow depth (< 2.54 m).

Our results show that low-frequency GPR (250 MHz) has the potential to probe the shallow subsurface to depths of 2.34 to 3.58 m in arid, volcanic terrain. The setting we used to processing our GPR data helped improve the interpretability of our GPR images and can be used as a guideline to design a GPR survey on Mars Home Plate. The geological and geophysical setting of Home Plate is similar to what we observe at Kilbourne Hole, NM (e.g., cross-bedded pyroclastic flow deposit, basalt flow deposit, volcanic blocks and sags features, size of volcanic blocks and thicknesses of their ash bed). Therefore, we suggest that a similar GPR survey could be conducted on either a robotic or human exploration mission to study features such as Home Plate on Mars. The results could be used to reveal important paleohydrologic conditions of ancient Mars. It is also appears on several researches that different volcanic deposits with different characteristics can interact with the radar beam differently (e.g. Haggy et al., 2007) and further laboratory study on the electrical properties of Martian volcanic deposit may be needed in order to design GPR surveys for Mars. In conclusion we provided here a quantitative paleohydrogeological interpretation from our GPR surveys and a survey approach to perform a GPR survey on a terrestrial volcanic setting. Our research strongly supports the idea that we can use GPR surveys to study paleohydrogeologic conditions on Mars.

Table 1. List of physical parameters.

Variables	Units	Descriptions
E_k	J	Kinetic energy of the eruption
M_f	kg	Mass of volcanic fragments including melt and pyroclastic deposit
M_w	kg	Mass of meteoric water in a phreatomagmatic eruption
M_m	kg	Mass of magma or melt in a phreatomagmatic eruption
M_w / M_m	-	Water to magma mass ratio or gas to magma ratio
V_o	m/s	Initial gas expansion velocity
τ	s	Time constant of gas expansion phase
V_e	m/s	Velocity at impact of volcanic blocks or gas expansion velocity
t	s	Travel time of the volconic block to its dropping location
n	-	Gas to rock fragments mass ratio
ε	F/m	Electrical permittivity
σ	S/m	Electrical conductivity
$ß$	dB/m	Attenuation rate
v	m/ns	Velocity of radar waves
z	m	Depth of radar reflector beneath the surface
Tv	ns	Arrival time or the time radar wave returned to the receiver
R	m	Radial distance from center of the eruption
R_0	m	Radial distance from crater rim where gas reached its maximum velocity
R_d	m	Radius of volcanic dike
d	m	Depth of the dike
R_c	m	Radius of the crater rim
x	m	Lateral distance from the crater rim (in Cartesian coordinates)
θ	radian	Open angle of the orifice to the center of the eruption
ρ_i	kg/m^3	Density of volcanic blocks (3100 kg/m^3)
ρ_g	kg/m^3	Atmospheric density or density of the gas cloud (4.7 kg/m^3)
g	m/s^2	Earth's gravitational acceleration (9.81 m/s^2)
φ	m	Volcanic block size
C_d	-	An empirical atmosphearic friction factor
$\varphi_{sag,\ GPR}$	m	Volcanic sag size measured from radargram
$\varphi_{sag,\ field}$	m	Volcanic sag size measured from the field
$\varphi_{blocks,}\ \varphi$	m	Volcanic block size derived from an empirical relationship

Table 2. Radial distance, GPR-determined volcanic sag size, volcanic block size, and terminal velocity for GPR line 6.

Radial Distance from Crater Rim (m)	GPR Sag Size (Y) (cm)	Volcanic Block Size (φ_i) $\varphi = (0.147Y) + 23.215$ (cm) *	Calculated Terminal Velocity $Ve=[(4\ \varphi_i\ \rho_i\ g)/(3C_d\ \rho_g)]^{1/2}$ (m/s) **

Range	113.46-132.21	81.01-103.58

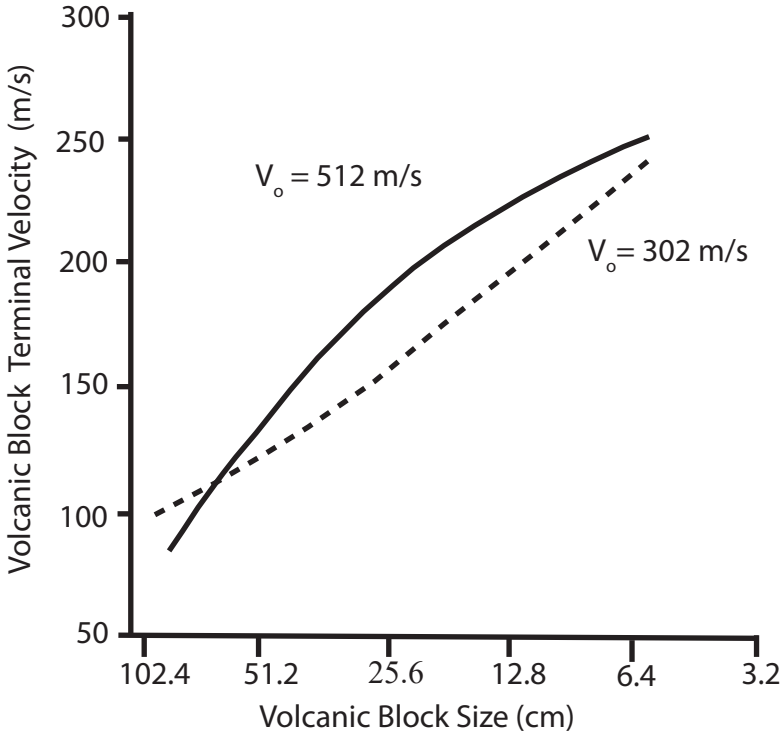

Figure 1. Relationship between the volcanic block terminal velocity and the sizes of volcanic blocks for two different initial gas velocities. Solid line represents the relationship if the initial gas velocity is 512 m/s and dotted line represents the relationship if the initial gas velocity is 302 m/s. Modified from Wilson (1999).

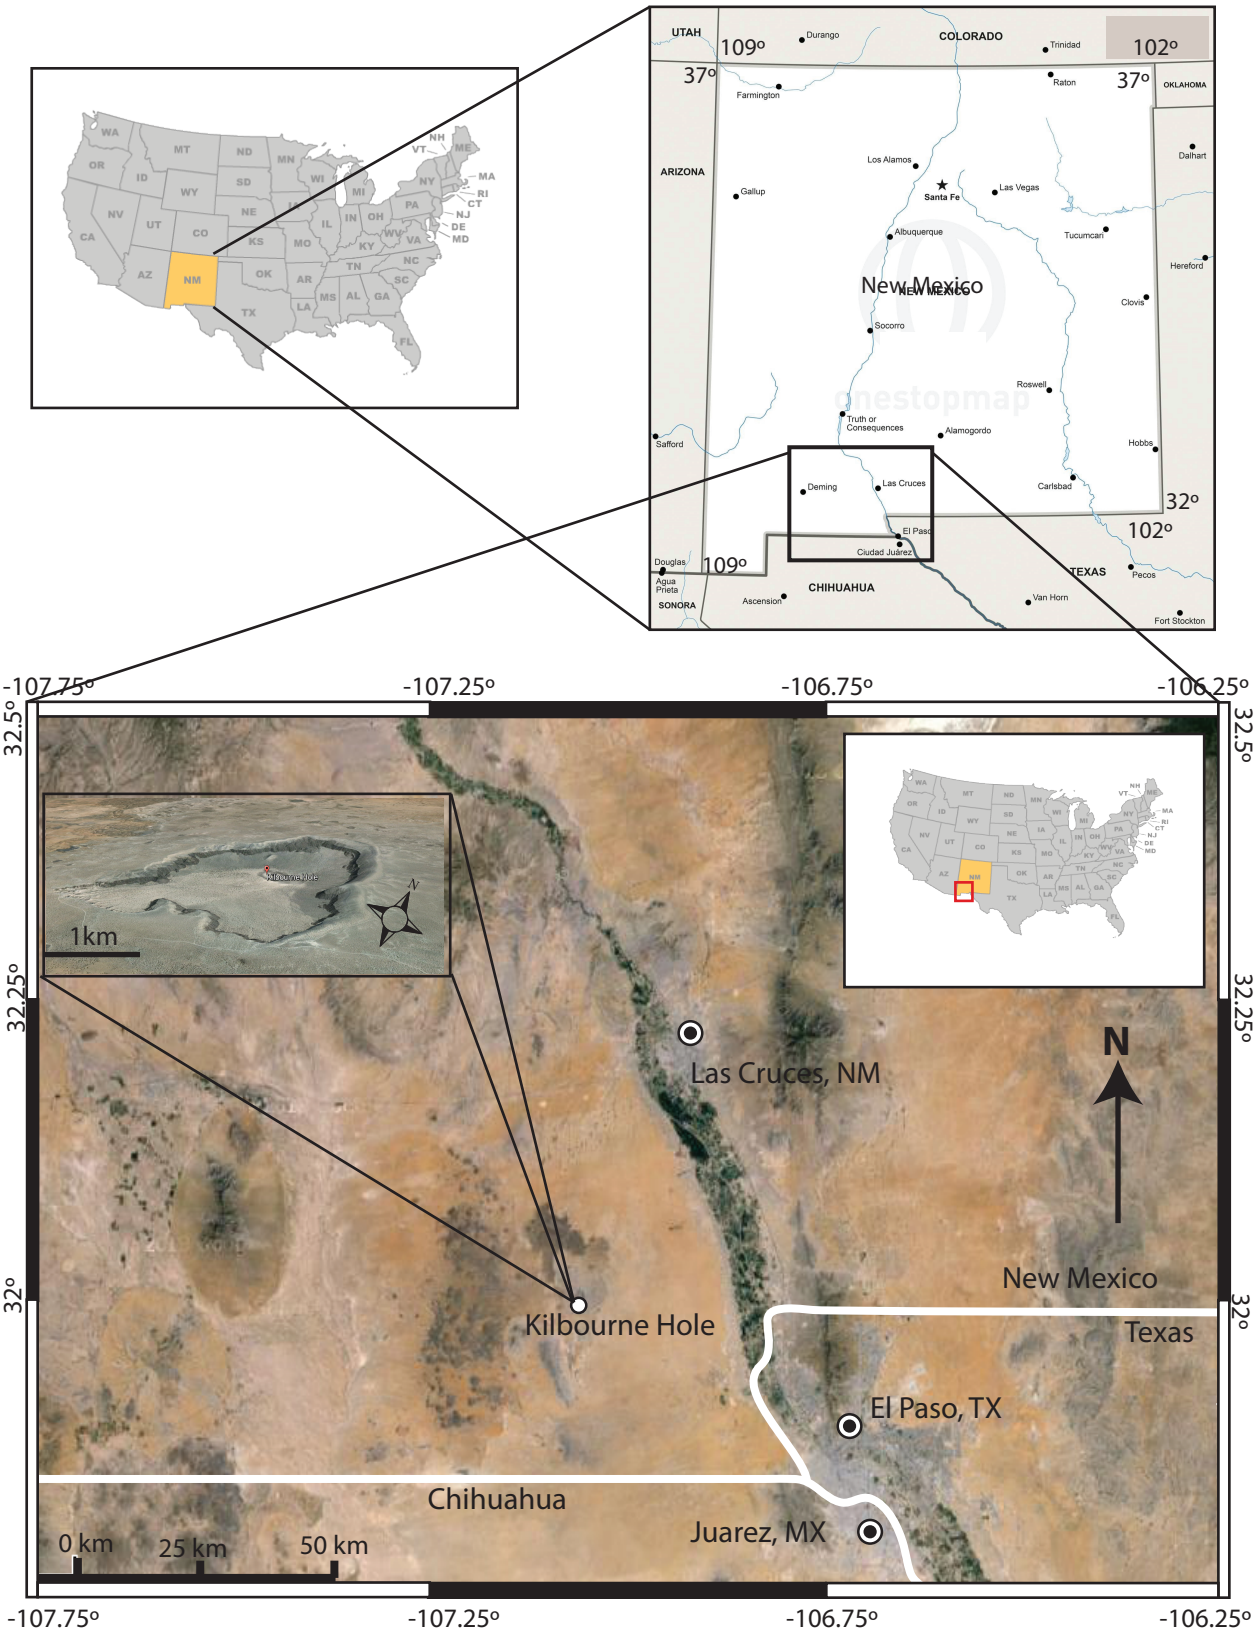

Figure 2. Location of Kilbourne Hole in southern Doña Ana County, New Mexico (imagery from Google Earth, 2008).

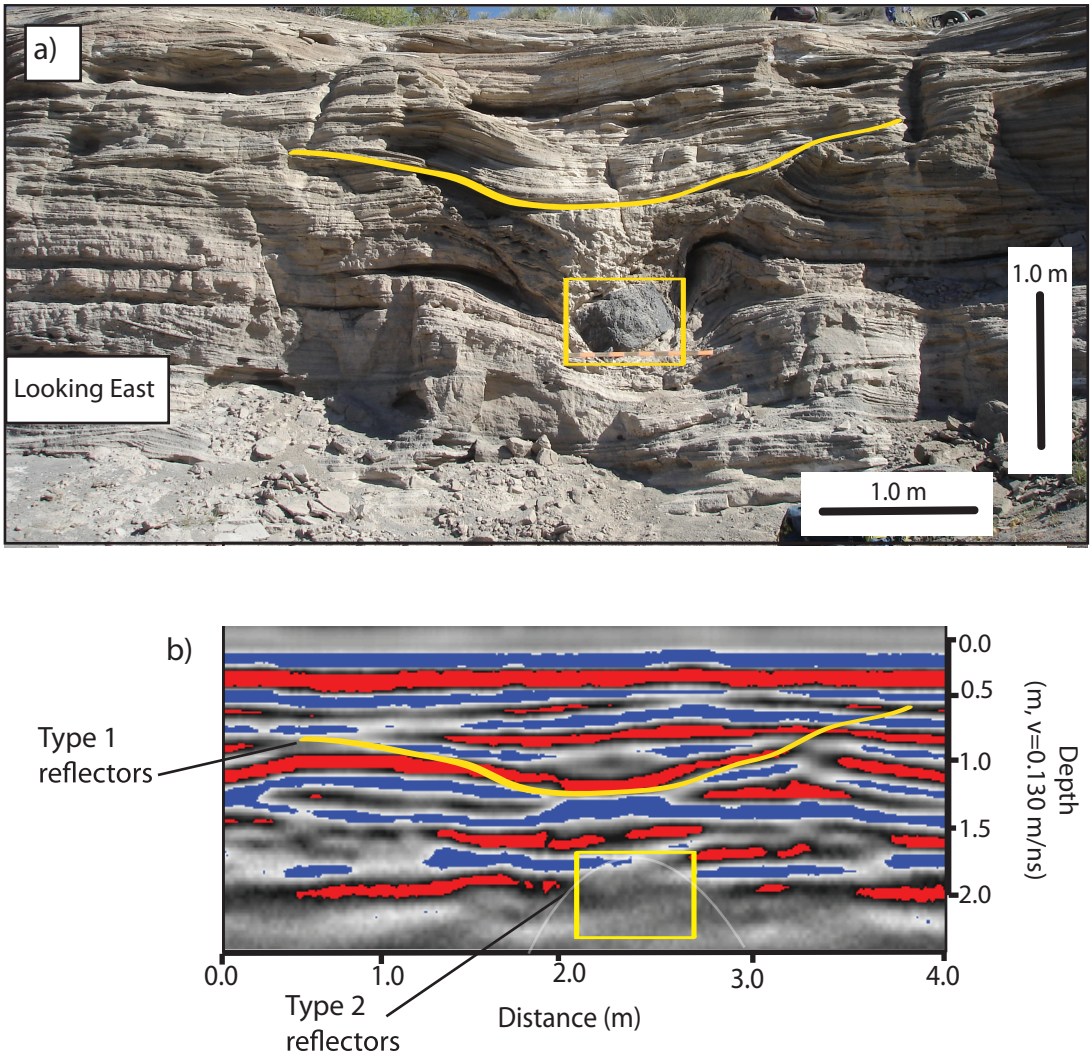

Figure 3. (a) Outcrop of a volcanic block and sag at Kilbourne Hole. Yellow box enclose a basaltic volcanic block feature. Yellow line marks the volcanic sag. (b) GPR image of the outcrop shown in (a), illustrating two types of reflectors. Type 1 reflectors are strong, continuous, smooth, undulating reflectors and correspond to features of pyroclastic deposits called volcanic sags (yellow line). Type 2 reflectors are dim and chaotic and correspond to basaltic volcanic blocks (yellow box). On some occasions, a hyperbolic reflector can be seen at the location of the volcanic block (white line was added as a demonstration).

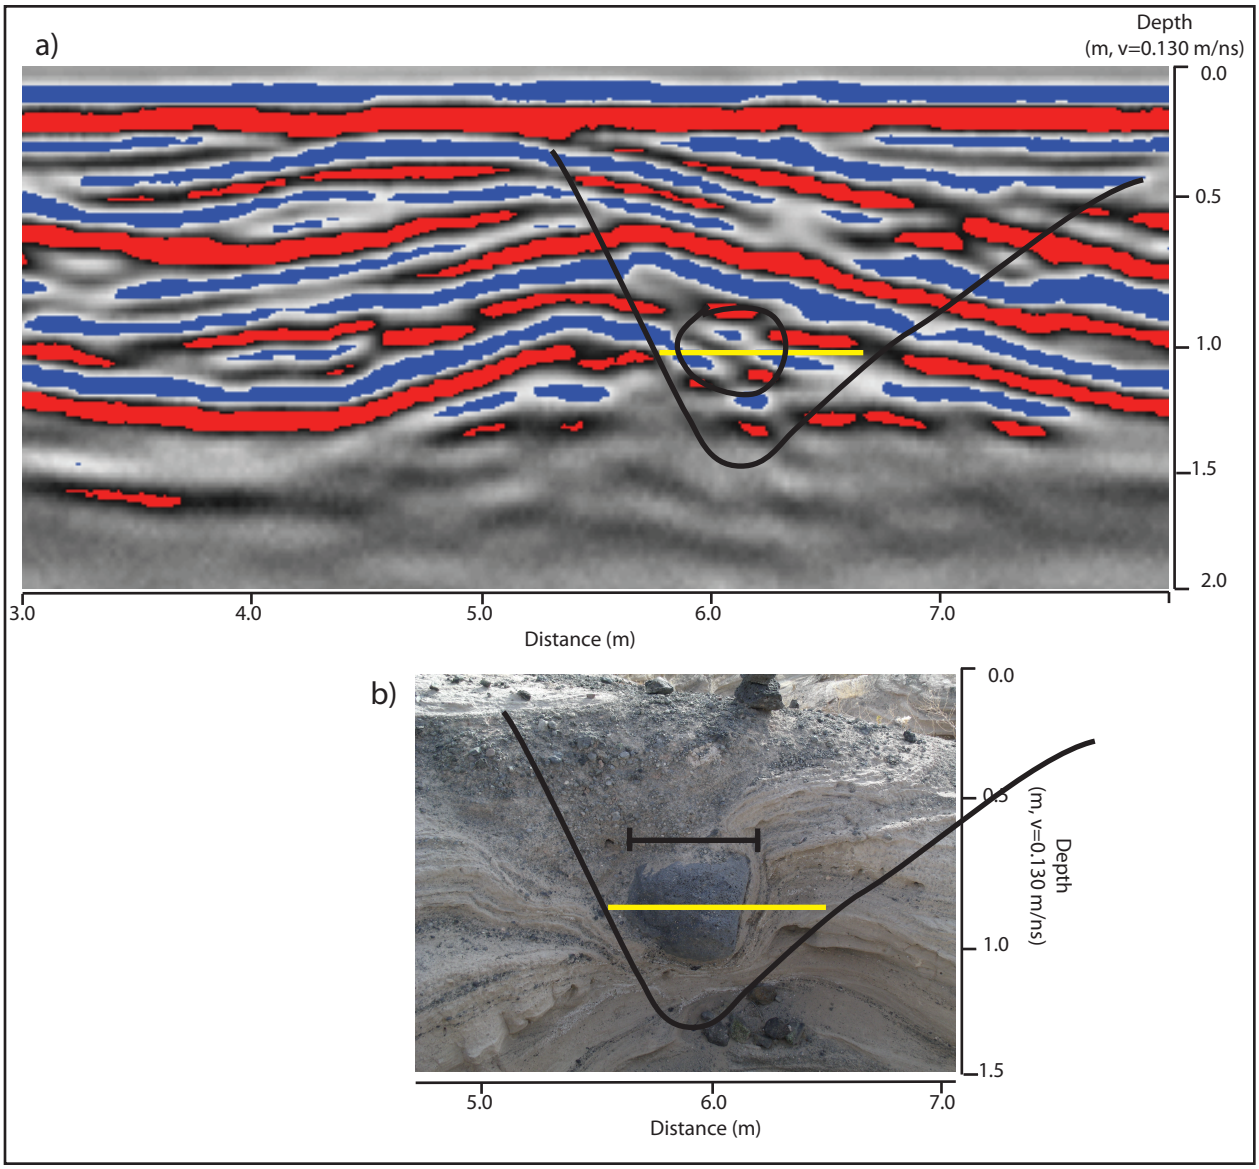

Figure 4. (a) Width measurement of a volcanic sag on GPR image. The widths of volcanic blocks cannot be measured on our GPR images because their reflections are dull and ambiguous. (b) Measurement of volcanic sags and blocks in the field. The yellow line marks the width measurement of the sag. The bracket represents the widest part of the volcanic block where the width of the block was measured.

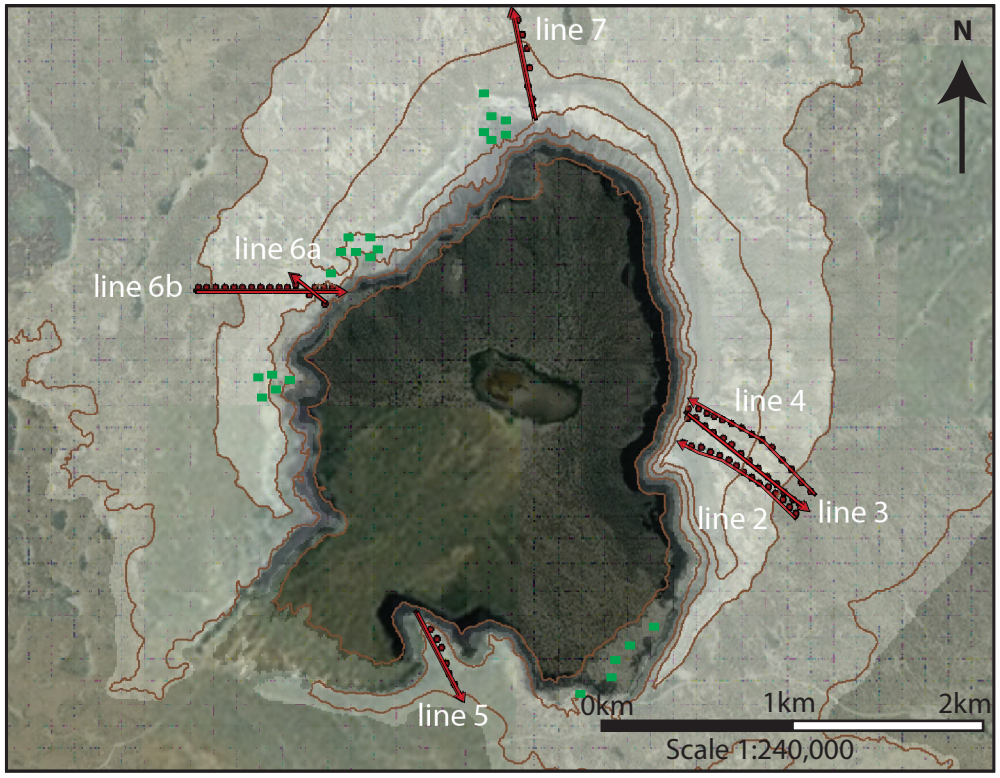

Figure 5. Location of GPR lines. Red arrows indicate direction of the GPR survey (away or toward the crater rim). Red dots indicate the location of long GPR surveys lines. Green rectangles indicate the location of twenty-nine short GPR survey lines that was performed to calibrate the volcanic sag size measurements. Base map is the 1:24,000 scale topographic map of Kilbourne Hole (U.S Geological survey, 2010).

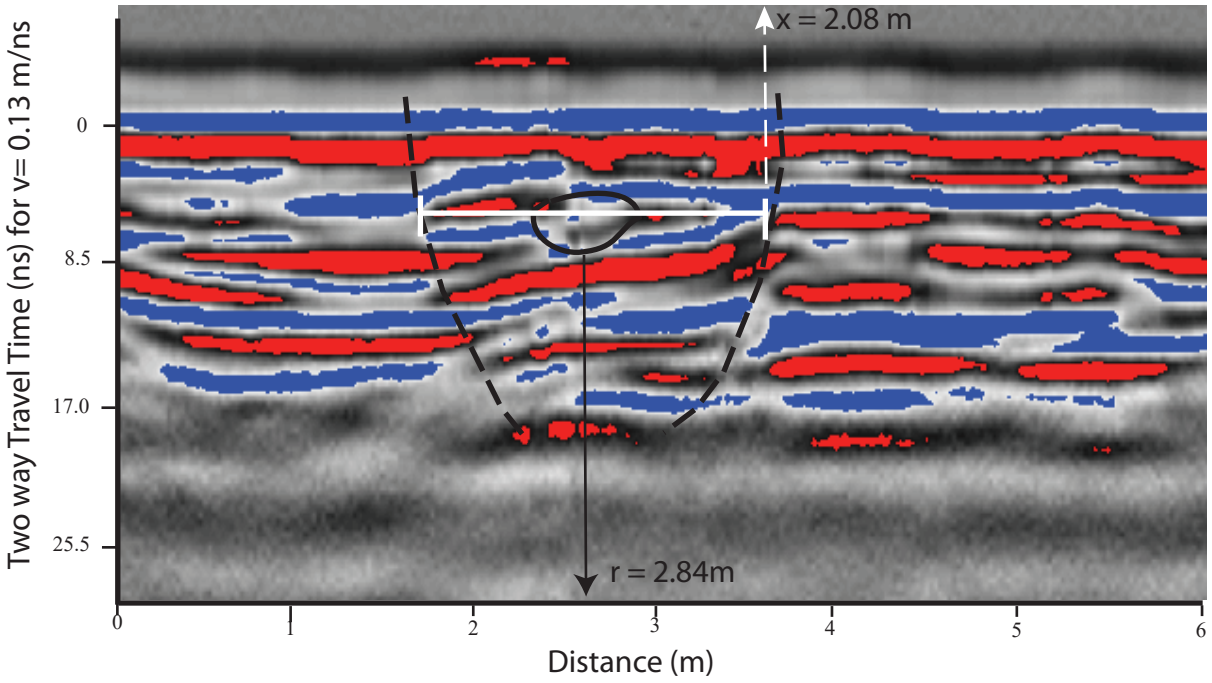

Figure 6. An example of a volcanic sag and associated block on a small section of GPR survey line 4. Plotted on the x-axis is the horizontal distance from the crater rim (in m) and plotted on the y-axis is the two-way travel time (in ns) of the GPR reflectors. Dashed lines highlight a reflection from a volcanic sag (Type 1 reflector). The oval marks a reflection from a volcanic block (Type 2 reflector). The size of the volcanic sag is represented by a white line. The horizontal distance of the sag from the crater rim (r) is 2.84 m.

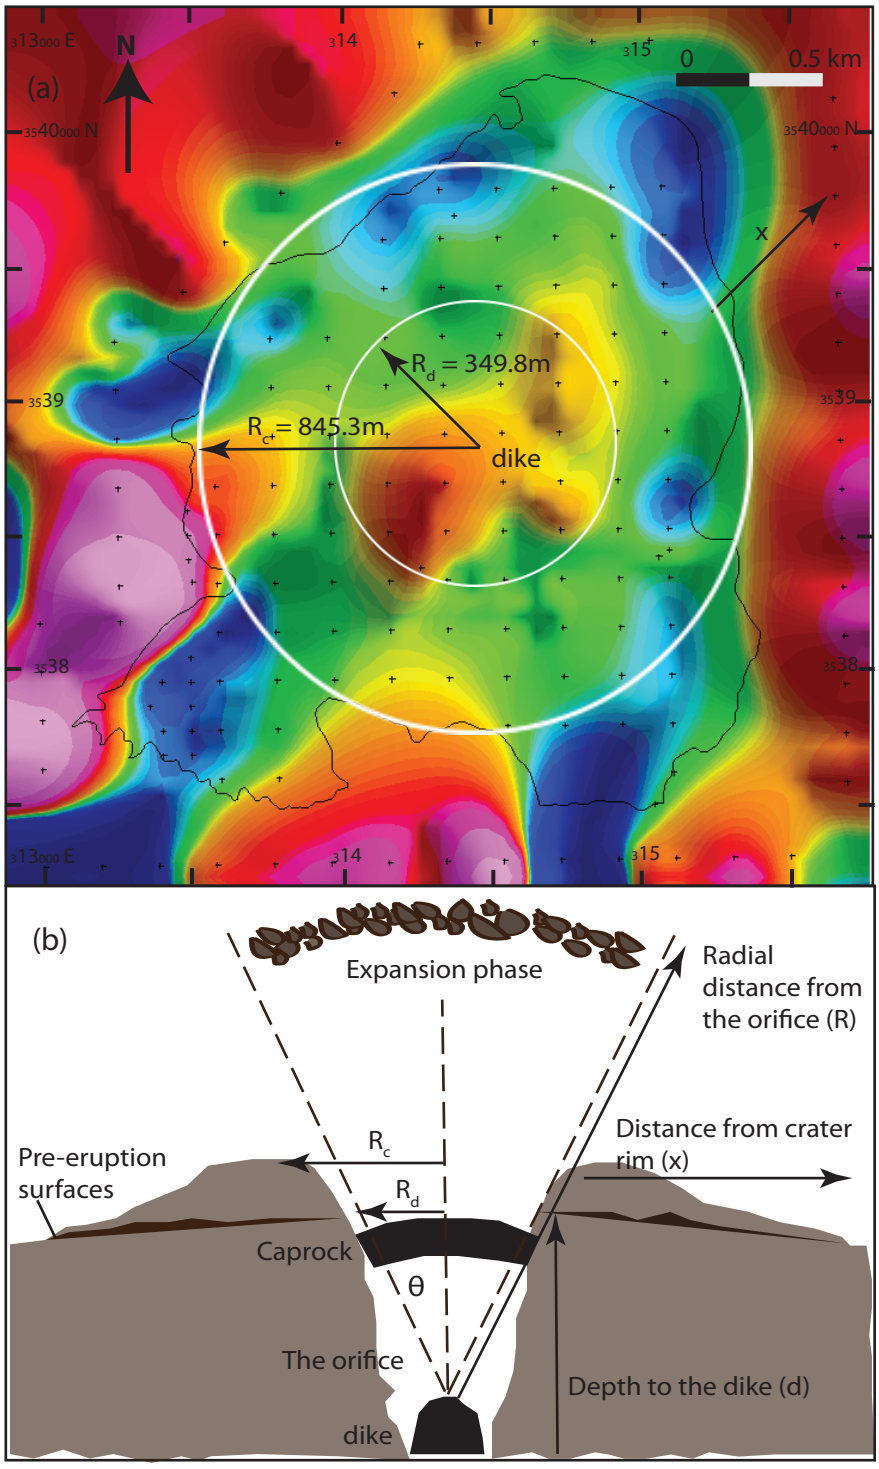

Figure 7. Structure and physical dimensions of Kilbourne Hole. (a) A magnetic anomaly map (Rhodes and Hurtado, 2012) of Kilbourne Hole showing the location of high magnetic anomalies in the center of the crater (interpreted to be dikes) and high magnetic anomalies around the crater rim that correspond to basalt flows). We consider the orifice of the explosion to be the area (of radius R_d) above the dikes, and we use a best-fit circle to the modern crater rim to estimate the crater radius (R_c). (b) A cross-sectional view of Kilbourne Hole illustrating the relationship between radial distance and horizontal distance from the orifice. The radial distance (R) is a cosine function of the horizontal distance (r). Modified from Rhodes and Hurtado (2012) and Fagents and Wilson (1995).

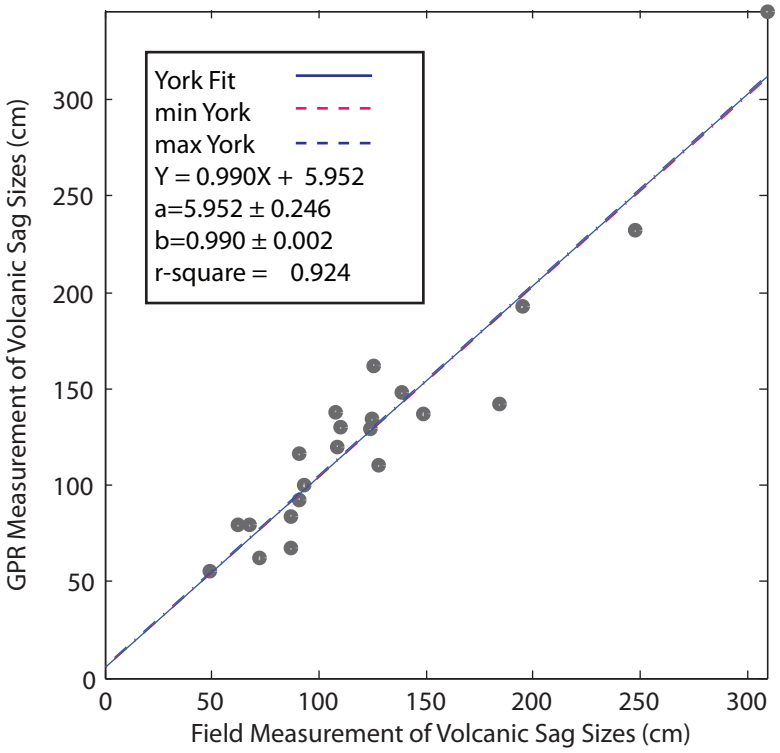

Figure 8. The relationship between volcanic sag sizes measured from the field and volcanic sag sizes measured from GPR profiles at Kilbourne Hole. This relationship is used to relate the width of a volcanic sag on the GPR profile to the actual width of the volcanic sag in the field. Uncertainties are shown by the light grey ovals and are smaller than the symbol size.

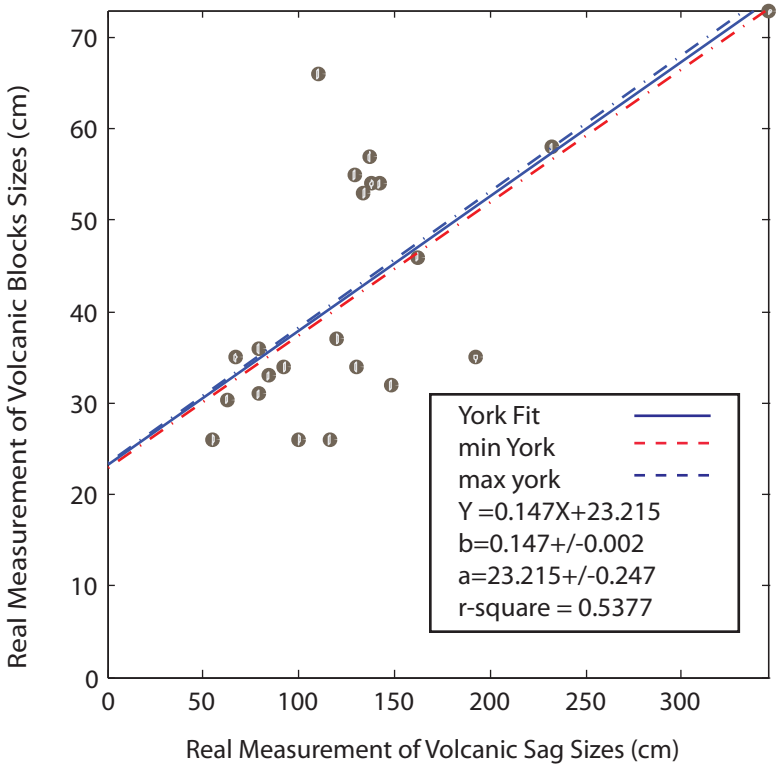

Figure 9. The relationship between actual volcanic block sizes and volcanic sag sizes at Kilbourne Hole measured in outcrop. This relationship is used to relate the actual width of a volcanic sag to the actual width of its associated volcanic block. Data uncertainties are shown by the light grey ovals and are smaller than the symbol size.

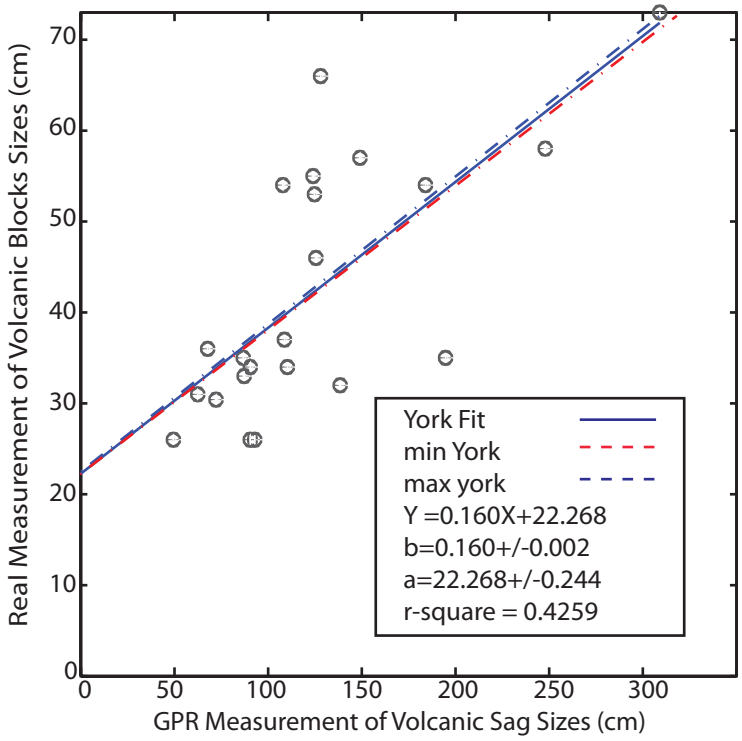

Figure 10. The relationship between the actual volcanic block sizes and volcanic sag sizes measured on GPR profiles at Kilbourne Hole. This relationship is used to relate the width of a volcanic sag on the GPR profiles to the actual width of its associated volcanic block. Data uncertainties are shown by the light grey ovals and are smaller than the symbol size.

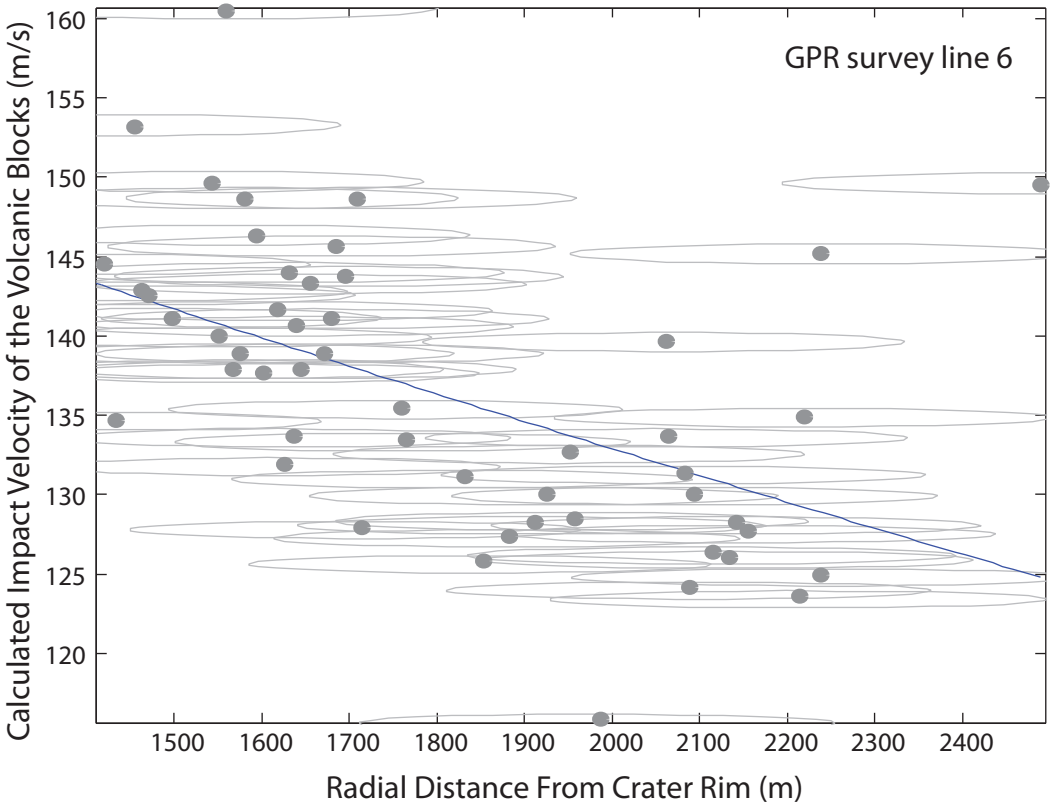

Figure 11. Impact velocity of volcanic blocks versus the radial distance from the vent of the volcanic blocks along GPR line 6. Grey ovals represent uncertainties of these two sets of data. Blue line represents an exponential relationship between the data sets.

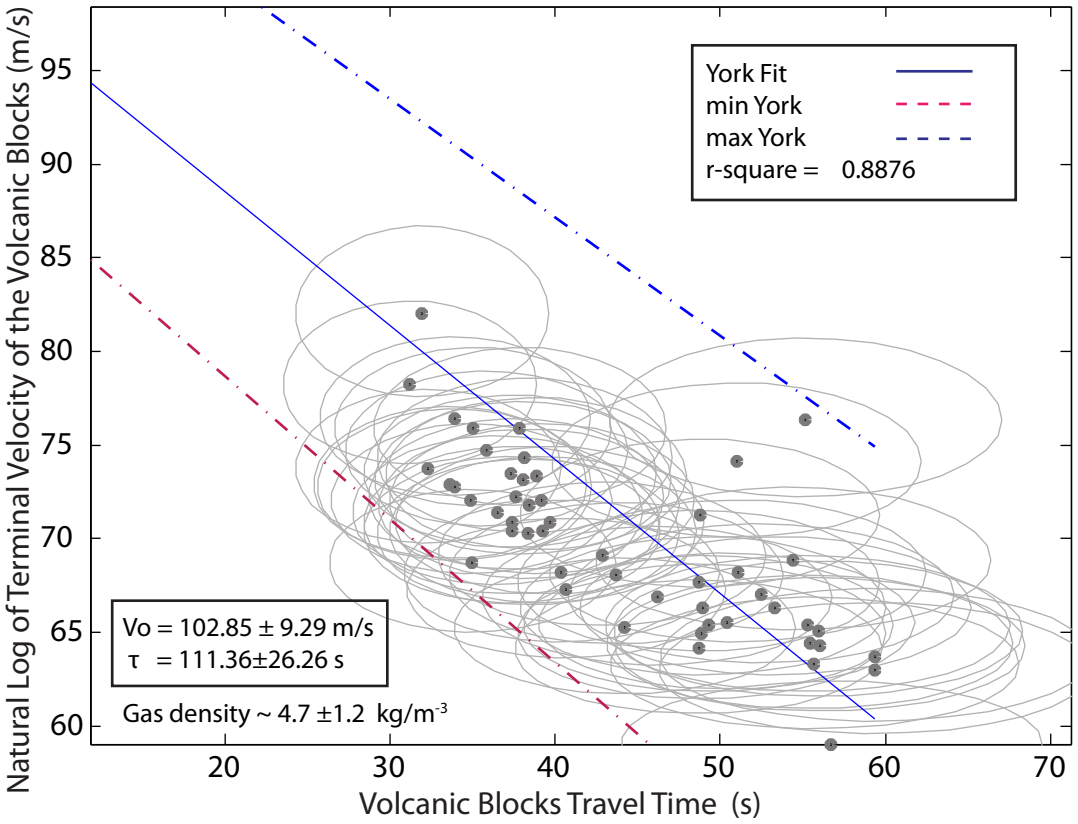

Figure 12. Linear relationship between the natural logarithm of terminal velocity of the volcanic blocks ($log_e V_e$) versus travel time to terminal location (t). The data shown here were retrieved from volcanic sags and blocks found along GPR survey line 6. The results of other survey lines are included in Table 3. Uncertainties in the data are shown by the light grey ovals. The solid blue line represents the York best fit. The dashed blue lines represent the maximum margin of York best fit. The dashed red lines represent the minimum margin of York best fit.

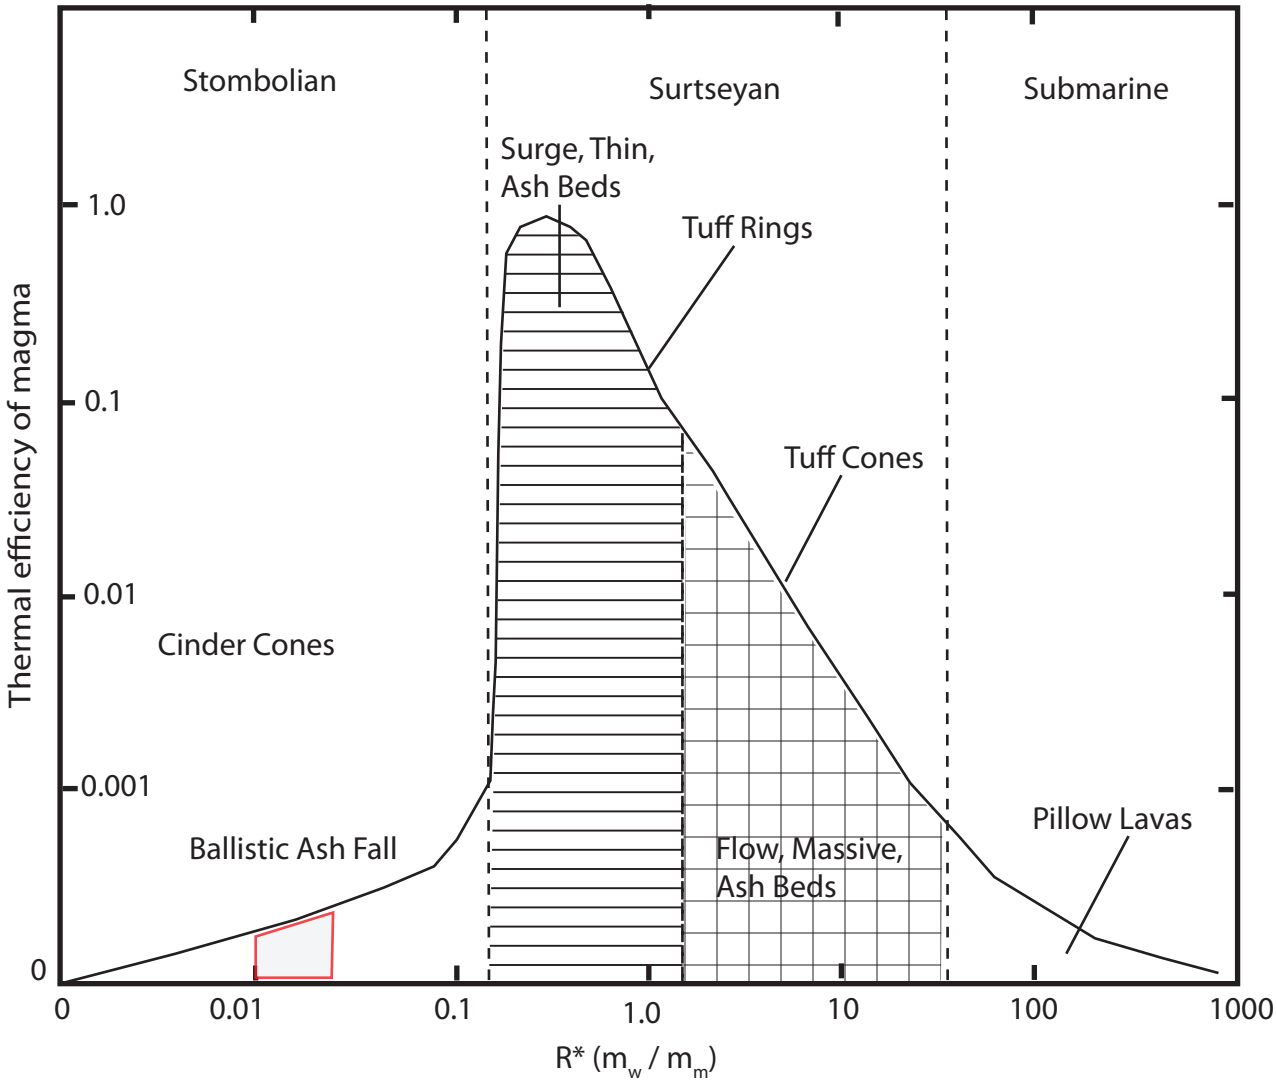

Figure 13. Ranges of thermal efficiency of phreatomagmatic eruption is shown as a function of water to magma mass ratio. Ranges are indicated types of eruptions (Strombolian, Surtseyan, and submarine) as well as the corresponding landforms and depositional facies (adapted from Wohletz and McQueen, 1984). Shaded red box indicates ranges of water to magma mass ratio (0.01- 0.02) predicted for Kiblourne Hole eruption.

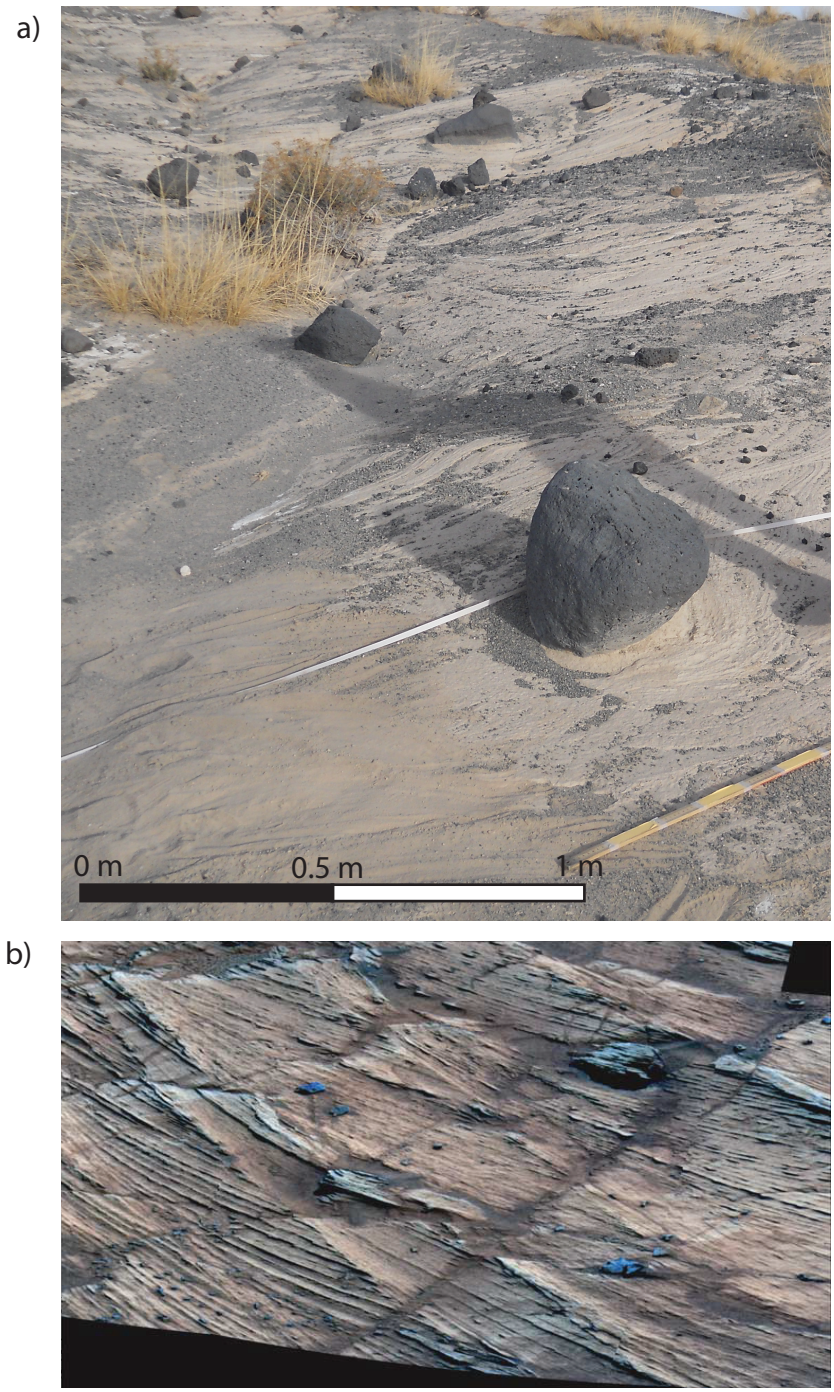

Figure 14. a) Cross bedded tuff ring, volcanic blocks, and volcanic sags found on the west rim of Kilbourne Hole. The image is a true color photograph taken by the authors in November 2014. b) High-angle cross bedding, volcanic blocks, and volcanic sags found on Home Plate, Mars. The mosaic image is a false color stretch photograph. The horizontal distance across the lower part of both images is approximately 1.5 m. (Squyres et al., 2007).

Appendix A: Maximum Gas Expansion Velocity Analysis

The routine of this code is based on the procedure suggested by Rhodes and Hurtado (2014). This code is design to determine the maximum gas velocity that ejected volcanic block from Kilbourne Hole eruption. The code was written on MATLAB 2012b. I adapted York's regression method (York, 2004) and implement it in this code to solve for the least square best fit of my data. The data input is an excel file format of 6 column. Column 1 of the excel file must be the size of the volcanic sag (in cm). Column 2 of the excel file must be the uncertainty of size of the volcanic sag (in cm). Column 3 and 4 are the size of the volcanic block (in cm) and the uncertainty of the volcanic block (in cm) Column 5 is radial distance of the volcanic block from the orifice of ejection in meter. Column 6 is the uncertainty of the radial distance. The output result of this code are: a velocity curve plot of the volcanic blocks (Terminal velocity vs, radial distance), York fit of the velocity curve with propagate uncertainty and r-square value of the regression, and result vector contain value of the maximum velocity of the gas expansion and the time constant of gas expansion phase.

Appendix B: Volcanic Clast Size Distribution at Kilbourne Hole

This appendix is in an excel format. It stored both field and laboratory measurement of Rhodes and Hurtado, 2014 GPR surveys at Kilbourne Hole. Rhodes and Hurtado (2014) performed a total of 6 long GPR surveys at Kilbourne Hole to identified buried volcanic blocks and sags. They measured the size of volcanic sags and the distance of the volcanic sags from the orifice of Kilbourne Hole. From the measured volcanic sag, we calculated the size of each volcanic block and its terminal velocity. The measurements and calculations of each GPR surveys line are in separate sheets of the excel file. These data sheet can be arranged to be compatible with the MATLAB code in Appendix A. Appendix B is also served as an input for Appendix-A.

Appendix C: Plots of Maximum Gas Expansion Velocity Analysis

We applied the code routine from Appendix A to the volcanic blocks data from the total of six survey transects (Appendix B) and produced the plot results showing here in Appendix C. The plots in Appendix C are the display of York's regression and least square best-fit including the r-square values of the York's regression and least square best fit. The plot shows data points and area of the uncertainties of the input data. Each plot yield three linear equations, which are minimum York's best fit, maximum York's best fit, and York's best fit. The code routine from Appendix A then further calculated the final result values, which are the maximum velocity of the gas expansion and the time constant of gas expansion phase from the slope and constant of those linear equations. The final results contain uncertainties and propagated uncertainties. We used Taylor (1997)'s method to propagate the uncertainties from the input data into our calculated results. The plots show in this appendix C are from survey transect 7, 5, 4, 3, and 2. The plot from survey transect 6 is showed in Figure 12 as an example of our results and methodology for Chapter 3.

Abstract

A mass concentration (mascon) is a region that contains a large positive gravitational anomaly. Mascons on the Moon are associated with some (but not all) impact basins, but the geologic processes that form them are not yet fully understood. We hypothesize that a combination of uplifted lunar Moho, impact melt sheets, and brecciated crust creates the gravity signature of lunar mascon basins. To test this hypothesis, we utilize the lunar gravity field measured by the Gravity Recovery and Interior Laboratory (GRAIL) mission to reconstruct the history of lunar mascon basin formation and associated magmatic activity. We perform preferential filtering on the free-air anomaly map derived from the GRAIL lunar gravity model GL0660A. Using the preferential filtering method, we isolate the gravity anomalies associated with structures at 16.2 km and 30.0 km depth. We construct four 2D inversion models from the filtered gravity data to visualize the internal structure of lunar mascon basins. We conclude from our 2D inversion models that the parameters that determine the gravity signatures of mascon basins are: (1) the extent of the impact-melt sheet; (2) the depth to the mantle; and (3) the thickness and the density of the surrounding crust.

Keywords: lunar geophysics, GRAIL, mascon basins, inverse modeling, preferential filtering, gravity anomaly separation, mantle rebound, impact melt sheets

1. Introduction

The geology of the Moon is dominated by the impact process, and large impact structures can be found across the lunar surface. Impact features that are larger than 300 km in diameter are called impact basins. The geology of impact basins is very complex and includes impact melts and breccia, faults and fractures, and induced volcanic activity (Bratt et al., 1985; Neuman et al., 1996). Throughout lunar geologic history, there have been more than forty large impact basin-forming events. Among these forty impact basins are some that possess abnormally high positive gravity anomalies (Figure 1). These gravity anomalies, called mascons ("mass concentrations"), are the most striking and prominent features of the lunar gravity field (Muller and Sjogren, 1968). The origin of lunar mascon basins and their unique gravity signal is not yet fully understood. One paradox is that not all large impact basins are mascon basins, so there must be processes other than impacts that are involved in mascon formation. Another paradox is that large impact events excavate and remove mass, so, therefore, they should yield negative gravity anomalies instead of positive gravity anomalies. Models of the lunar crust (Sjogren and Smith, 1976; Zuber et al., 1994; Weiczorek and Phillips, 2000) show that mascon basins do indeed have very thin crustal thicknesses as expected. In light of this, what contributes to the positive gravity anomalies of mascon basins is not yet known.

In this research, we demonstrate the use of lunar geophysics as a tool to resolve the internal structure of mascon basins and shed light on the processes responsible for their formation. We utilize the lunar gravity field measured by the Gravity Recovery and Interior Laboratory (GRAIL) mission to reconstruct the history of lunar mascon basin formation and associated magmatic activity. Utilizing lunar gravity data for this purpose is not straightforward because the lunar crust has been highly affected by impacts that have changed the topography

and have produced impact melts that have altered subsurface densities and porosities (Zuber et al., 2013). Previous analyses of the high-resolution GRAIL gravity maps have shown that over 98% of the gravity anomalies are associated with topography, and only 2% represent subsurface structures (Zuber et al., 2013). In order to retrieve gravity anomalies that represent interior structure rather than these surficial characteristics, we perform low pass filtering and preferential filtering (Spector and Grant, 1970; Guo et al., 2013) of the free-air anomaly map derived from GRAIL lunar free-air gravity model GL0660A to filter out the high frequency gravity signal and selectively filter the gravity signal from the depth of 16 km and 30 km.

In this paper we describe: (1) the low pass filtering method used to isolate the contributions to the lunar gravity anomaly associated with lunar interior structure; (2) the power spectrum depth analysis method (Spector and Grant, 1970) and the preferential filtering method (Guo et al., 2013) used to isolate lunar gravity anomalies associated with specific depths; and (3) 2D inversion modeling of the filtered gravity anomaly data used to reconstruct the internal structure of mascon basins. We hypothesize that the anomalous positive gravity anomalies associated with mascon basins may be the result of a combination of: (1) shallow high-density mantle; (2) moderate density impact melt sheets; (3) low-density, brecciated crust; and/or (4) high density igneous intrusions.

2. Background

2.1 Mascon Basins

Lunar mascons are found associated with some (but not all) impact basins. The major mascons are shown in Figure 1 (Wilhelms et al., 1985; Spudis, 1996; Cook et al., 2000): Serenitatis, Humorum, Imbrium, Orientale, Crisium, Nectaris, Smythii, and Grimaldi. Konopliv et al. (2001) proposed that there are six additional mascons on the lunar farside (Figures 1 and 2): Hertzsprung, Moscoviense, Korolev, Freundlich-Sharonov, Coulomb-Sarton, and Dirichlet-Jackson. Six out of the eight mascon basins on the lunar nearside are on or around the area called Oceanus Procellarum (Figure 1). Oceanus Procellarum itself is not considered a mascon basin, but it is one of the most geologically complex regions on the Moon (Andrews-Hanna, 2013).

On a free-air gravity anomaly map (Figure 2), mascon basins have a bull's-eye pattern comprising a central positive anomaly surrounded by an annular negative anomaly and an outermost annular positive anomaly. As observed by Namiki et al. (2009) (Figure 1), there are differences in the character of the mascon basins on the lunar nearside (Type I mascons) compared to those on the lunar farside (Type II mascons). Type I mascons have central positive anomalies that are extensive and wide, and they are surrounded by weak and subtle negative gravity anomalies (Figure 2). In contrast, Type II mascons are characterized by more distinct rings of positive and negative gravity anomalies, yielding a more pronounced bull's-eye pattern (Figure 2). In addition, the amplitude of the positive gravity anomalies associated with Type I mascons is ~250-500 mGal, whereas the amplitude of the positive gravity anomalies associated with Type II mascons is ~400-900 mGal. In the GRAIL GL0600A free-air gravity model (Figure 2), Orientale, Mendel-Rydberg, Lorentz, and Humboldtianum show more affinity to the

farside mascons than to the nearside mascons. These basins show more pronounced bull's-eye patterns and have positive gravity anomalies with amplitudes consistent with Type II mascons (~600 mGal). Therefore, we group them as Type II mascons.

Namiki et al. (2009) suggest that the difference in the positive gravity anomaly amplitude between Type I and Type II mascons is likely due to differences in super-isostatic, dynamic uplift of the mantle during the thermal evolution of the Moon. Namiki et al. (2009) also speculate that the central positive gravity anomaly peak and the negative gravity anomaly annulus of Type II mascons are associated with: (1) brittle deformation of the lithosphere; and (2) mare volcanism. Brittle deformation induces a negative gravity signal because porous and brecciated rocks have lower density than the surrounding crust. Mare basalt and associated intrusions induce a positive gravity signal because they have a greater density than the surrounding crust.

Muller and Sjogren (1968) suggested that the positive gravity anomalies in Type I mascon basins are not associated with mare basalts. They argue this based on the observation that the magnitude of the anomaly exceeds what mare basalt could produce. Similarly, Andrews-Hanna et al. (2013) showed that mare basalts in Oceanus Procellarum are too thin to explain the mascons within Oceanus Procellarum. Using a hydrocode model that simulates the isostatic rise of the lunar mantle following an impact, Melosh et al. (2013) demonstrated that the bull's-eye gravity anomaly of lunar mascon basins can, instead, be explained by mantle rebound, flexure of the crust, and the cooling and contraction of a body of impact melt. Jozwiak et al. (2014) further speculated on the contribution of mare basalts to the gravity anomalies associated with lunar mascons. They proposed that the density contrast between high-density intrusions along

fractures and the low density, highly brecciated lunar crust on the impact basin floor should produce the observed high positive gravity anomalies.

Head and Wilson (1992) suggested that mare basalt alone could be responsible for the origin of the gravity anomalies in mascon basins. Mare basalts are fined grained basalts with olivine microphenocrysts and generally high density (3270 ± 10 to 3460 ± 50 kg/m^3). They are confined to the topographic depressions formed by lunar impact basins (Baldwin, 1971), predominantly on the lunar nearside. Head and Wilson (1992) estimated the total volume of mare basalt (~1 × 10^7 km^3) as a function of basin size and amount of basin subsidence. They suggested that the mass of mare basalt is large enough to cause impact basins to subside, resulting in the subsequent accumulation of thickened sequences of mare basalt and a positive gravity anomaly (Head and Wilson, 1992). However, this hypothesis does not explain the gravity signature of mascon basins that do not contain extensive mare basalt such as Mare Orientale. The majority of mare basalt is found in Mare Imbrium, with lesser amounts in Serenitatis, Crisium, Imbrium, and Humorum, and the least in mare Orientale. The mare Orientale basalts formed in early lunar history (3.8-3.6 Ga) whereas those in Mare Imbrium, Serenitatis, Crisium, Imbrium, and Humorum erupted later in lunar history (3.6-3.2 Ga; Head and Wilson, 1992).

2.2 Oceanus Procellarum

Oceanus Procellarum covers a 3,000-km wide area on the lunar nearside (Wieczorek and Phillip, 2000) and is considered to be one of the most geologically complex regions on the Moon (Warren and Wasson, 1979; Lawrence et al., 1999; Jolliff et al., 2000). Oceanus Procellarum is

thought to be the remnant of an ancient giant impact, although the impact origin of Oceanus Procellarum is still under debate (Wieczorek and Phillips, 1998). While Oceanus Procellarum contains local positive gravity anomalies associated with mascons (e.g. Mare Imbrium, Mare Sarenitatis, Mare Crisium), Procellarum itself is not considered a mascon basin (Sjogren and Wimberly, 1974; Wieczorek and Phillips, 1998; Joliff et al., 2000).

Oceanus Procellarum is the location of the youngest Mare basalts on the lunar nearside, particularly in Mare Imbrium and Mare Serenitatis (~1.5-1.6 b.y) (Hiesinger et al., 2000; Hiesinger et al., 2003). Hiesinger et al. (2003) estimated that the mare basalts in Oceanus Procellarum cover an area >4,000,000 km^2 and are several hundred meters deep. The composition of this basalt is dominated by potassium, rare-earth elements, and phosphorous (KREEP) and the area in which these KREEP basalts are found is called the Procellarum KREEP Terrane (PKT; Joliff et al., 2000). KREEP itself is a geochemical component found in only some lunar impact breccia and basaltic rocks and which contains significant amounts of elements that are usually concentrated in the magma during fractional crystallization. KREEP also contains significant amounts of the heat-producing elements uranium, thorium, and potassium (Warren and Wassan, 1979; Warren, 1985). It is estimated that the KREEP contains 300 times more uranium and thorium than chondrites (Joliff et al., 2000). Because of the large quantity of radiogenic heat producing elements KREEP contains, previous workers (Spudis et al., 1991; Ryder, 1997; Haskins, 1998) have hypothesized that KREEP may have been the heat source that contributed to the high volume of mare volcanic activity on the lunar nearside. Wieczorek and Phillips (2000) focused on the role of sub-crustal heating for PKT in the thermal evolution of the Moon. Wieczorek and Phillips (2000) suggested in their model that there was a 10 km thick KREEP-rich layer with radiogenic heat producing elements emplaced beneath the PKT crust at

60 km depth. Wieczorek and Phillips (2000) suggested that the KREEP-rich layer should have been in a molten to partially molten state for most of the Moon's history, and persists long after the solidification of the Moon magma ocean. In their model, the PKT was represented as a spherical cap, axisymmetrically located above the conduction zone of this KREEP-rich layer. This model is also marginally consistent with elevated heat flow observed at the Apollo 15 site.

This long-lived molten KREEP-rich layer was speculated to have been produced by global differentiation during the cooling of lunar magma ocean. Wieczorek and Phillips (2000) stated that during the crystallization of the lunar magma ocean, KREEP-rich later were molten and trapped between the solid upper crust and the Moho. The composition of KREEP-rich layer is deriving from the residual the final crystallization product (urKREEP) from the early Moon's magma Ocean itself (Wieczorek and Phillips, 2000). Both Oceanus Procellarum and the KREEP-rich layer below it were subsequently modified by impact cratering process (Wieczorek and Phillips, 2000). Large impact events, such as that which formed Mare Imbrium, may have penetrated the entire lunar upper crust, exhuming KREEP from the lower crust and olivine rich rocks from the mantle (Wieczorek and Phillips, 2000). Grimm (2013) agreed with Wieczorek and Phillips, 2000 but also suggested that the possible model of the KREEP-rich layer below the PKT in Oceanus Procellarum was instead an ancient impact that resulted in the uplift of the lunar Moho (Grimm, 2013).

We speculate that, since not all impact basins are mascon basins, mascon formation is not dependent on the impact process alone but also requires other processes. We suggest that the existence of the molten KREEP-rich layer beneath the Oceanus Procellarum may play a major part of mascon formation. We postulate that the impact event done on the molten or partially molten KREEP basalt layer may disrupt and excavate the still molten KREEP basalt magma

chamber. Pre-impact crustal structure can control the amplitude of mantle relaxation and subsequent crustal deformation (Namiki et al., 2009). For example, ductile deformation after an impact can increase the density contrast between the impact basin and the surroundings due to extension of the impact melt pool (Namiki et al., 2009). Brittle deformation can instead decrease the density contrast between the impact basin and the surroundings due to brecciation or intrusions facilitated by deep fracture zones caused by the impact (Namiki et al., 2009). Wieczorek and Phillips (2000) suggested that impact into a molten KREEP basalt magma chamber was also the reason why the materials from an ancient lunar magma ocean (urKREEP) were able to mix and melt into KREEP material.

2.3 Lunar Crustal Models

In this research, we utilize an inversion modeling method to gain insight into the formation lunar mascon basins. *A priori* geologic information (e.g., lithologies, densities, sizes and thicknesses of subsurface structures, etc.) is needed to constrain and to reduce the uncertainties of these inverse models. We refer to several crustal models by previous researchers (e.g. Wieczorek and Phillips, 1998; Yamamoto et al., 2010; Yamamoto et al., 2012; Wieczorek et al., 2013; Zuber et al., 2015; Andrews-Hanna et al., 2014) to constrain our models.

Based on surface reflectance data collected by the spectral profiler on the Kaguya spacecraft, the lunar crust is olivine-dominated with small quantities of admixed plagioclase (Yamamoto et al., 2010; Yamamoto et al., 2012). GRAIL crustal thickness models imply an average lunar crustal thickness of 34-43 km (Wieczorek et al., 2013), which is substantially thinner than previously thought (~60 km; Wieczorek and Phillips, 1998). The recent GRAIL crustal thickness models predict that the crust is nearly absent (<5-km thick) beneath nearside

impact basins such as Crisium and also beneath the farside Moscoviense basin (Wieczorek et al., 2013). The GRAIL crustal models also indicate that the average density of the lunar upper crust is markedly low (2580 ± 170 kg m^{-3}) due to impact fracturing (Wieczorek et al., 2013). The average lunar crustal (upper and lower crust) density is 2,900 kg m^{-3} and the average lunar mantle (upper and lower mantle) density is 3,400 kg/m^3 (Wiezorek and Phillips, 1998). Huang and Wieczorek (2012) estimate the lunar crustal density to be 2,590-2,870 kg m^{-3}. Kiefer et al. (2014) measured the bulk density of lunar rock samples and suggested a crustal density of 2,550 kg m^{-3} and a mantle density of 3,220 kg m^{-3}.

Spudis et al. (2014) showed that impact basins on the Moon are only partly flooded by mare basalt. A major portion of material exposed on the floor of lunar impact basins is the impact melt sheet. Zuber et al. (2015) demonstrated the thickness of the impact melt sheet in Mare Orientale is ~10 km thick. The bulk density of impact breccia and impact melt is 2,450-2,850 kg m^{-3} (Kiefer et al., 2014), however, the grain density of impact breccia and impact melt is as high as 2,990-3,100 kg m^{-3}. This high grain density implies that impact melt is primarily composed of mantle material, a result supported by hydrocode simulations of large impacts that eject most crustal material from the resulting basin (Potter et al., 2013; Melosh et al., 2013; Vaughan et al., 2013).

3. Methodology

3.1 GRAIL

The Gravity Recovery and Interior Laboratory (GRAIL) mission (Zuber et al., 2014) was designed to remotely map the lunar gravity field to address fundamental questions about lunar evolution. Understanding the lunar gravity field can provide insights into lunar internal structure, bulk composition, heat flow, and the duration of volcanism and tectonism. For this study we used the Radio Science Digital Map Product (RSDMAP) data products available from the Planetary Data System (PDS) LGRS RDR archive. These are derived from the GL0660A GRAIL lunar gravity model (Zuber et al., 2013). GL0660A is a degree and order 660 spherical harmonic model (truncated to degree and order 320) (Zuber et al., 2013). Because a single crustal density of 2,560 kg m^{-3} was assumed to create the available GL0660A Bouguer gravity anomaly map (Zuber et al., 2013), it may not be completely free of all topographic and terrain effects. We therefore choose to instead use the GL0660A free-air gravity anomaly map (Figure 2) for the purposes of this study. The free-air gravity anomaly map has a resolution of 4 pixels per degree, or ~7.6 km per pixel on a reference sphere with semi-major-axis radius of 1,738 km (Zuber et al., 2013). Each pixel gives the free-air gravity anomaly in milligals (mGal).

3.2 High-Pass Filtering and Low-Pass Filtering

We considered several kinds of filters (high pass, low pass filter and preferential filter) to understand the lunar free-air gravity signal spectrum and to isolate and suppress interfering signal from lunar shallow subsurface. We perform both low pass and high pass filtering on the GL0660A free-air gravity anomaly data. To perform a low pass filtering and remove the gravitational potential of short-wavelength, high-frequency anomalies arising from near surface

geology, we applied a low-pass filter operator to the free-air gravity anomaly map in the frequency domain. We developed a Gaussian low pass filter operator at the cutoff wavelength 10-degree. We then imported the GL0660A free-air gravity anomaly data into MATLAB and converted the free-air anomaly map from spatial domain to frequency domain. In frequency domain we convolve the free-air gravity signal with the low pass filter operator. The resulting low pass filtered signal is transformed back to the spatial domain, to obtain the low pass filtered free-air gravity anomaly map (Figure 3). With this low pass filter, only the gravity signals that are larger than 10-degree are isolated and the gravity signal produced from the geological features that are smaller than the 10-degree are suppressed. To perform high pass filtering, we created a high-pass filter operator by subtracting the low-pass filter operator from 1. By applying this high-pass filter operator to the unfiltered GL0660A free-air gravity anomaly signal in the frequency domain, we removed the long wavelength signal from the free-air gravity signal. We then converted the high pass filtered gravity signal back to the special domain to obtain a high-pass filtered gravity map that reveals short-wavelength, high-frequency anomalies belonging to near surface geology (Figure 4).

3.3 Power Spectrum of the Gravity Signal

The gravity signal is an ensemble of the gravitational effects of geologic features of varying depths, widths, thicknesses, and densities. To understand the various contributions to the gravity signal, we employ a power spectrum analysis approach. In the spatial domain, the total free-air gravity anomaly, $g_{fa}(x,y)$, is the sum of gravitational anomalies originating from the deep subsurface, $g_d(x,y)$, and gravitational anomalies originating from the shallow subsurface, $g_s(x,y)$ (Nettleton, 1957; Powlowski., 1994):

$$g_{fa}(x,y) = g_d(x,y) + g_s(x,y) \qquad (1).$$

Similarly, in the frequency domain, the Fourier power spectrum (P) of the total free-air gravity signal is the sum of the radially averaged power spectra of deep subsurface (P_{i+1}) and shallow subsurface (P_i) components (Naidu, 1968):

$$P = P_1 + P_2 + \cdots + P_i + P_{i+1} \qquad (2).$$

The power spectrum of the gravity signal due to a subsurface component i is an exponential function (Dampney et al, 1969; Guo et al., 2013):

$$P_i = s_i e^{-2k_i h_i} \qquad (3),$$

where h_i is the depth to subsurface layer I; k_i is the angular, or radial, frequency of its power spectrum; and the constant s_i is the strength, or intensity, of the gravitational signal associated with that layer (Dampney et al, 1969; Guo et al., 2013). Combining Equations (2) and (3) yields (Guo et al., 2013):

$$P = s_1 e^{-2k_1 h_1} + s_2 e^{-2k_2 h_2} + \cdots + s_i e^{-2k_i h_i} \qquad (4).$$

To analyze the power spectrum of the unfiltered lunar free air gravity signal, we imported the non-filtered GL0660A free-air gravity anomaly data into MATLAB (see Appendix A). We transformed the data into the frequency domain and calculated the radially averaged power spectrum (P) using the raPsd2d command (Figure 5). Similarly, to analyze the power spectrum of the low pass filtered and high pass filtered lunar gravity signal, we imported the low pass filtered and high pass filtered GL0660A free-air gravity anomaly data into MATLAB (see Appendix A), respectively, then transformed the data into the frequency domain and calculated

the radially-averaged power spectrum (P) using the raPsd2d command on both sets of data (Figure 6 and 7).

3.4 Power Spectrum Depth Analysis

To understand the geological process that contributes to lunar free air gravity signal, we apply average radial power spectrum analysis (Guo et al., 2013) to the unfiltered free-air gravity anomaly map, the high-pass filtered free-air gravity anomaly map, and the low-pass free-air gravity anomaly map. By this analysis, we can estimate the depth of the gravity signal and also gain *a priori* information about lunar crustal structure (e.g. thickness of the crust, depth to mantle, and depth of gravitational anomalies). Knowing the depth of gravity signal allows us to decide whether the gravity signal is appropriate to model with the given data. With the known depth of gravity signal we also are able to constrain the model. Upon the justification that the depth analysis results from all three types of lunar gravity anomaly maps are in agreements and the confirmation that the gravity signal from the shallow subsurface were completely removed from the low pass filtered gravity anomaly map, we then continued to the next step of preferentially filtering on the low pass free air gravity map only.

We used a method modified from Guo et al. (2013) and Spector and Grant (1970) to define the depth of gravity signal. This method relates average depths to source to rate of decay of the gravity power spectra. Under the presumption that: 1) the gravity signal from the same source depth with uniform distribution should also yield similar range of power spectrum and similar power decay rate (Spector and Grant, 1970); 2) the gravity signal from each source depth are independent from once another (Spector and Grant, 1970). We calculated the depths of the

gravity signal from the slope of power spectrum analysis plots (Figures 5-7). The shifting in decay rate of the power spectrum marks depth variation of the gravitational source. Our depth calculation method modified from Spector and Grant (1970) was implemented in MATLAB (see Appendix A). Using MATLAB, in the frequency domain, we plotted radially averaged power spectra (P) as a function of radial frequency, k, of all three lunar gravitation anomaly maps on a logarithmic scale (Figures 5-7). The MATLAB user must select the component of the radially averaged power spectrum (P) if the gravity signal profiles can be divided into sub-profiles following Spector and Grant's theory. P can be divided into several components (P_1, P_2,…, P_i) each representing the power of an individual subsurface layer (i.e. Equations (2) and (4)). Each component P_i contains several sub-profiles within it. To make sure that the assumed depth values from our calculations are in the closest agreement to the field condition as possible, we generated depths values from a synthetic component of P_i, called $P_{i,cal}$. Then by using least square method we can significantly reduce the variation of the mean and standard deviations between the sub-profiles (P_i) in comparison with the whole profile ($P_{i,cal}$). In MATLAB, we apply a piece-wise linearization (using the lsq_lut command in MATLAB) to fit straight-line segments to each power spectrum component (P_i). These fits provide the best fit synthetic power spectrum of $P_{i,cal}$ for each layer (P_i) . Each segment of the power spectrum is from a different depth inside lunar crust, and we can estimate the depth from the piece-wise best-fit segments. Depth (h_i) for each subsurface component can be calculated (Guo et al., 2013) using (Wiener et al., 1949; Guo et al., 2013):

$$h_i = \frac{P_i(k_i) - P_{i+1}(k_{i+1})}{4\pi(k_i - k_{i+1})} \qquad (5),$$

where k_i and k_{i+1} are the starting and ending radial frequencies of a given spectral segment and $P(k_i)$ and $P(k_{i+1})$ are the values of the radially averaged power spectra (in cycles per km) at the

start and end of a given spectral segment (Spector and Grant, 1970; Guo et al., 2013) (Figures 5-7).

Because picking spectral segments on the power spectrum plot can be very subjective, in additional to the radially averaged power spectra plot, we also plot the first- and second-derivatives of the power spectrum (Figure 5-7). The first- and second-derivative plots reveal the continuum of the Moon's gravitational signal in term of power spectrum and radial frequency. Where the changes in the power spectrum decay rate are significant (from minimum rate to maximum rate or vice versa), there is a prominent spike (positive spike or negative spike) on the first- and second-derivative plots. We can use those spikes to define the locations where the power spectrum trend had shifted. The first- and second-derivative plots allow the selection of spectrum segments to be done more precisely, less subjectively, and more consistently.

Now that user can identify the variation of source depth on the radially averaged power spectra more accurately and precisely, following Wiener's filtering theory (Wiener 1980; Guo et al., 2013), the user can selectively filter the desired gravity signal spectra from a source depth of interest. This preferentially filtering method is described in Section 3.5. We further studied the selected signal using gravity 2D inversion method (see Section 3.6).

3.5 Preferential Filtering and Gravity Anomaly Separation

The preferential filtering method is similar to frequency-domain Wiener filtering (Spector and Grant, 1970; Wiener, 1949). We use this method to filter the low-pass filtered free-air gravity anomaly data at a specific bandwidth in order to selectively retrieve the gravity signal associated with a specific depth (Spector and Grant, 1970; Wiener, 1949; Guo et al., 2013). The

Wiener preferential filtering operator we use is in this form (Spector and Grant, 1970; Wiener, 1949):

$$W_{pfi} = \frac{P_{i,cal}}{P_i} \qquad (6),$$

where P_i is the power spectrum of the gravity signal of subsurface component i and $P_{i,cal}$ is the calculated synthetic power spectrum of subsurface component i.

To perform the preferential filtering, we imported the low pass filtered GL0660A free-air gravity anomaly data into MATLAB. We used Equation (6) to generate the Wiener preferential filtering operator (W_{pfi}) to separate gravity signal from geological layer i at the depth of h_i apart from other gravity signal assembly. By replacing the obtained radially-averaged power spectrum component (P_i) and the calculated synthetic power spectrum ($P_{i,cal}$) from the previous Section 3.4) into equation (6), we retrieve the Wiener preferential filtering operator (W_{pfi}). In MATLAB, using matrix multiplication command, we apply the W_{pfi} filtering operator of the target layer to our low pass filtered gravity data in the frequency domain to filter the gravity signal from target layer i (Guo et al., 2013; Weiner, 1949). We then apply an inverse Fourier transformation to the result to yield the filtered free-air gravity anomaly associated with target layer i in the spatial domain (Figure 8 and 9; see Appendix A). With the preferential filtering method we make the assumption that gravity anomalies isolated with a given depth are independent of gravity anomalies at other depths, specifically with no amplification and downward continuity between each other.

3.6 Two-Dimensional Inversion Modeling

To resolve the internal structure of the lunar crust, we built inverse models from the low-pass and preferentially filtered free-air gravity anomaly data using *Geosoft Oasis Montage v. 6.2*. Because *a priori* geologic information (e.g. seismic data, boreholes, magnetic data, etc.) for the Moon is limited, our models were mainly constrained using surface geological features such as the distribution of mare and highlands lithologies (Weiczorek et al., 2006; Kiefer et al., 2012). The results of the gravity models are particularly dependent on the densities we choose for these lithologies.

The models include the following density values: for mafic intrusions, we use the density of mare basalt (3,150 $kg.m^{-3}$) (Zuber et al., 2014; Weiczorek et al., 2006; Kiefer et al., 2012); for the lunar crust we use an average density of 2,560 $kg.m^{-3}$ (Zuber et al., 2014; Weiczorek et al., 2013; Keifer et al., 2012); and, for impact melt, we use a density of 2,770 $kg.m^{-3}$ (Kiefer et al., 2015; Zuber et al., 2015). The lunar crustal thickness, also used as a constraint in our models, is approximately 10-30 km in the PKT and 35-55 km in the lunar highlands (Miljkovic et al., 2015; Vaughan et al., 2013;). When modeling depths greater than 30 km, we use a density of 3,000 $kg.m^{-3}$ for the lower crust (Vaughan et al., 2013) and 3,300 $kg.m^{-3}$ for the upper mantle (Vaughan et al., 2013).

The results of our power spectrum depth analysis, (see Results), are also used as an additional depth constraint. We also adjusted our model based on *a priori* knowledge of the impact basin-forming processes. For example, *a priori* information previously indicated the thickness of impact melt sheet are speculated to vary from 1s-10s km thick (Zuber et al., 2015; Andrews-Hanna, 2014), so we adjusted and varied the thicknes of our model accordingly to see which thickness makes the most sense for our model. Most impacts that form craters >300 km in

diameter produce enormous volumes (>105 km^3) of impact melt (Abramov et al., 2012). Abramov et al. (2012) suggest, based on models of impact melt production and topographic data, that the impact melt produced by the Orientale-forming impact formed a 15.5 km thick impact melt sheet. Accordingly, the thickness of the impact melt sheets in our models is adjusted proportionally for impact basins that are larger or smaller than Mare Orientale.

We constructed a total of four 2D inversion models from the low-pass and preferentially filtered free-air gravity anomaly map. To begin model construction, we assigned a simple, two-layer crustal structure to each model in areas outside of mascon basins. The upper layer is the lunar crust and lower layer is lunar mantle. For mascon basins, we assigned a three layer crustal: (1) an uppermost impact melt sheet; (2) underlying brecciated crust; and (3) uplifted mantle at the bottom. Each component layer in the model was assigned an appropriate density, depth, and cross-sectional width. We then used Euler deconvolution (Phillips, 2007), as implemented in *Geosoft Oasis Montage v. 6.2*, to calculate the predicted gravity anomaly based on the thickness, size, and density each model component. The dimensions and densities of the modeled geologic bodies were iteratively adjusted to minimize the RMS misfit between the calculated gravity anomaly and the observed gravity anomaly. Models were considered reliable if the RMS misfit was less than 10%.

4. Results

4.1 Radially-Averaged Power Spectrum of the Lunar Gravity Signal

Figures 3 and 4 show the low-pass and high-pass filtered free-air gravity maps, respectively. The low-pass filtered gravity signal contains mostly long-wavelength, low-amplitude (3 to 96 mGal), and high-degree power spectrum. The high-pass filtered gravity signal contains mostly short-wavelength, high-amplitude (-77 to 156 mGal), and low-degree power spectrum.

Using the method of Spector and Grant (1970) to analyze the radially averaged power spectra of the unfiltered and filtered free-air gravity maps, we estimate the depths corresponding to the dominant gravity signals. We find that the unfiltered, lunar free-air gravity signal includes components at depths of 4.0 km, 8.8 km, 15.6 km, and 53.7 km (Figure 5). The power spectrum depth analysis of the high-pass filtered free-air gravity data shows short wavelength, high amplitude, and low degree power components at depths of 8.4 km, 8.9 km and 12.9 km (Figure 6). The power spectrum analysis of the low-pass filtered free-air gravity data suggests that long-wavelength, low frequency gravity anomaly sources are located at depths of 11.9 km, 16.2 km, and 30 km (Figure 7).

The unfiltered and high-pass filtered free-air gravity data is not appropriate for 2D inversion modeling because: (1) the depths obtained are all smaller than the Nyquist wavelength (~15.2 km, or twice the resolution) of the GL0660A free-air gravity data; and (2) the gravity signal of short-wavelength anomalies contains high amplitude noise (Figures 4 and 6) due to surface excavation produced by impacts and due to mare basalt that filled in the basins (Zuber et al., 2015). The most effective method to eliminate these high frequency signals from our

analysis is to only consider the low-pass filtered free-air gravity data. We believe the low-pass filtered free-air gravity data is more appropriate for 2D inversion modeling because: (1) the 16.2 km and 30 km depths obtained are larger than the ~15.2 km Nyquist wavelength; and (2) the 30 km depth is consistent with the average crustal thickness of the Moon (~34 km; Wieczorek et al., 2012). The 2D inversion model of the gravity signal from 30 km depth should, therefore, reveal the structure of the lunar Moho. The 16.2 km signal may be related to important crustal features such as the thickness of the crust under the PKT (Wieczorek et al., 2012), mare basalt (Zuber et al., 2015), intrusions (Zuber et al., 2015), and the uplifted Moho underneath large impact basins (Zuber et al., 2015). Because it is smaller than the Nyquist wavelength, we do not consider the 11.9 km depth in our modeling.

4.2 Low-Pass and Preferentially Filtered Free-air Gravity Anomaly Maps

Prior to modeling, we used the preferential filtering method (Section 3.2) to isolate the gravity anomalies associated with 16 km and 30 km depths from the low-pass filtered free-air gravity map. The results are shown in Figures 8 and 9. Figure 8 shows that the low-pass and preferentially filtered gravity anomaly map for 16 km depth has magnitudes between -10 and 102 mGal. Figure 9 shows that the low-pass and preferentially filtered gravity anomaly map for 30 km depth has magnitudes between -3 and 17 mGal. Dashed and solid white ovals in Figure 8 and 9 show the locations of Type I and Type II mascon basins. We found that all mascon basin features remain on both filtered maps. Both low pass filtering and preferentially filtering process does not remove the mascon basin features from the filtered maps. At 16 km depth, Type I mascons, which do not exhibit bull's-eye features, exhibit positive gravity anomalies with amplitudes from +50 to +102 mGal (Figure 8). At 30 km depth, Type I mascons, which also do

not exhibit bull's-eye features, exhibit positive gravity anomalies with amplitudes from +11 to +18.5 mGal (Figure 8). All Type II mascons have positive gravity anomalies with amplitudes between +30 and +50 mGal at a depth of 16 km and have amplitudes between +5 and +10 mGal at a depth of 30 km (Figure 9). Most of the Type II mascons do not exhibit bull's-eye features at 16 km depth, except for Mare Orientale and Mendel Rydburg, which do (Figure 8). To begin the modeling process, we select transects where the greatest positive magnitude of anomaly are found. Because positive gravity anomalies are normally associated with large density contrasts in the subsurface (Milsom, 2007), hence mascon basin should be allocated to the area of high positive gravity anomalies. At depths of 16 and 30 km, the largest positive anomalies (>100 mGal) are found along latitude 37°N in Mare Imbrium, a Type I mascon basin (Figure 8). At depths of 16 and 30 km, the largest positive anomalies associated with Type II mascon basins (~60 mGal) are found in Mare Orientale along latitude 20°S (Figure 9). Because of this, we choose transects along those latitudes for our 2D inversion modeling.

4.3 Two-Dimensional Inversion Model of the Low-Pass Filtered and Preferentially Filtered Free-air Gravity Anomaly

We constructed four 2D inversion models (Figures 10 and 11): (1) for 16 km depth along transect A-A'; (2) for 16 km depth along transect B-B'; (3) for 30 km depth along transect A-A'; and (4) for 30 km depth along transect B-B'. We are able to resolve the structure of major mascon basins in Oceanus Procellarum, the lunar near side, and the lunar far side. The RMS misfit between the inversion models and the filtered free-air gravity data is small. All misfits are less than 10 percent (4.0-9.7 %).

The 16-km model for transect A-A' suggests two 42-76 km diameter mafic intrusions beneath Oceanus Procellarum along latitude 37°N (Figure 10). The model also suggests bodies of impact melt with densities of 2,770 kg m^{-3} located within Mare Imbrium, Mare Serenitatis, Mare Crisium, Humboldtianum, and Moscoviense. The impact melt sheets do not appear to be symmetrical and their diameters vary. The diameters of the impact melt sheets beneath Mare Imbrium, Mare Serenitatis, Mare Crisium, Humboldtianum, and Moscoviense are 800-1000 km, 608-630 km, 364-486 km, 445-798 km, and 224-427 km, respectively (Figures 10). The thicknesses of the impact melt sheets in these basins also vary. The 16-km model for transect A-A' indicates the thickest impact melt sheet (extends to 25.14 km depth) is in Mare Imbrium. It also appears that there is no crustal material left below the impact melt sheet in Mare Imbrium. This is shown by the sharp transition from impact melt sheet to lunar Moho underneath Mare Imbrium and it suggests that the impact may have excavated the entire crust. The 16-km model for transect A-A' shows 3-6 km thick crust remains underneath Mare Serenitatis, Mare Crisium, Humboldtianium, and Moscoviense (Figure 10).

The 16-km model for transect B-B' indicates there are impact melt sheets in Mare Orientale, Mare Humorum, and Mare Nectaris (Figure 11). The diameters of the impact melt sheets within Mare Orientale, Mare Humorum, and Mare Nectaris are 170-308 km, 716-974 km, and 440-917 km, respectively (Figures 11). The thicknesses of the impact melt sheets in Mare Orientale, Mare Humorum, and Mare Nectaris are 18.4 km, 17.3 km, and 19.8 km, respectively. The 16-km model for transect B-B' suggests that the crust below Mare Orientale was not completely removed and that 8.9 km of crust remains (Figure 11). The model also shows that the crustal thicknesses underneath Mare Humorum and Mare Nectaris are 6.2-10.8 km (Figure 11). With no evidence of crustal removal due to mascon forming events, it also appears that the

thicker the impact melt sheet, the thinner the crust below the impact basin, as is the case in Mare Nectaris (Figure 11). Thicker impact melt sheets are likely due to larger impact events, which, as a result, also may remove more crust. The 16-km model for transect B-B' also suggests a 19-22 km diameter mafic intrusion beneath Oceanus Procellarum along latitude 20°S (Figure 11).

The 30-km models for transect A-A' and B-B' show that the lunar Moho has been uplifted to an approximate depth of ~30 km (Figure 10) beneath the northern latitude of Oceanus Procellrarum and to an approximate depth of ~22 km (Figure 11) beneath the southern latitude of Oceanus Procellrarum and to an approximate depth of 24 km underneath Mare Orientale (Figure 11).

All four models indicate the crustal thicknesses within the mascon basins on the lunar farside are ~10 km thicker than those on the nearside. The impact melt sheet within Mare Imbrium is the thickest (25.1 km). The second thickest impact melt sheet is found within Mare Nectaris (19.8 km). Although we constrained our models with the known densities of lunar lithologies (Keifer et al., 2015), in order to minimize the RMS misfits of the models we found that we must use a lower density than expected (2,460 $kg.m^{-3}$) for the crust underneath mascon basins. Kiefer et al. (2015) suggest that impact breccia can have a density as low as 2,450 $kg.m^{-3}$, similar to the density we use for the crust beneath mascons. This suggests that the crust beneath mascons could be highly fractured and its porosity increased substantially. This interpretation is also supported by other studies that show how large impacts can completely shatter the upper crust (Scott and Wilson, 2005; Milbury et al., 2015). Soderblom et al. (2015) studied the residual Bouguer gravity anomaly of the GRAIL data and concluded that the positive gravity anomaly values associated with mascon basins also correlate with high porosity in the surrounding crust. With these considerations in mind, we consider the low-density crust beneath

the mascons in our models to be brecciated crust underneath impact melt sheets. All four models indicate crust with a density of 2,460 kg m^{-3} below the impact melt sheets of most impact basins with the exception of Humboldtianum and Moscoviense, where the crust may not be brecciated as extensively, and Mare Imbrium where the crust was completely removed (Figures 10-11).

5. Discussion

Miljković et al. (2015) speculated during basin-forming events complete crustal excavation might have occurred in several of the largest impact basins on the nearside as well as the Moscoviense basin on the farside. Our results suggest that total crustal removal and mantle excavation are not as common as previously thought (Zuber et al., 2015; Wieczorek and Phillips, 1998; Miljkovic et al., 2015). Among the seven mascon basins included in our model transects, only Mare Imbrium may have completely lost its crust. Our results are compatible with those of Andrews-Hanna et al. (2014) who present an inversion model of Oceanus Procellarum using the GRAIL GL0420A Bouguer anomaly data. Their results suggest that Oceanus Procellarum is a mare filled depression and that the underlying feldspathic crust extends to a depth of 34 km. Below the feldspathic crust is uplifted lunar Moho (Andrews-Hanna et al., 2014). In some places underneath the Oceanus Procellarum, the uplifted lunar Moho can be as shallow as ~8 km from the lunar surface (Andrews-Hanna et al., 2014).

Our models suggest that the feldspathic crustal materials within Oceanus Procellarum are very porous and brecciated and that the thickness of this feldspathic crust in Oceanus Procellarum varies from 0 km to 22 km. The thickness of the feldspathic crust within major mascon basins such as Mare Serenitatis, and Mare Crisium is very thin (<5km) and, according to our model results, there is no crustal material left in Mare Imbrium. Our model also suggests that the maximum uplift of the lunar Moho (up to 22 km) occurred toward the south side of Oceanus Procellarum. This pattern in lunar Moho depths is compatible with the most recent GRAIL-derived lunar crustal thickness models (Wieczorek et al., 2013) that also predict the absence of the crust (<5 km) beneath some of the nearside impact basins.

Both of the 16-km models suggest several areas of large positive anomalies (>50 mGal) are associated with Type I mascon basins (Mare Imbrium, Mare Serenitatis, Mare Crisium, Humboldtianum, and Mare Nectaris) and smaller positive gravity anomalies (<25 mGal) are associated with Type II mason basins (Mare Orientale, Humboldtianum, and Moscoviense). Both 2D-inverse models from 16-km depth suggest that the positive gravity anomalies of large impact basins are the result of extensive crustal fracturing. The density of the crust below the impact basins in our model is lower than the average feldspathic crust, which may be because of impact-related brecciation and fracturing. We note that the highest positive anomaly of any mascon basin (Mare Imbrium) is caused by a body of moderate-density impact melt overlying a body of low-density fractured crust. Together, these bodies yield a high-density contrast, which causes a positive gravity anomaly signal.

Both 16-km models suggest two, 19-70 km diameter mafic intrusions underneath Oceanus Procellarum. Along the 20°S model transect, the model indicates one intrusion zone located approximately at 45°W. Along the 37°N transect, the model indicates two intrusion zones located approximately at 50°W and 100°E. The mafic intrusions revealed in our models are not associated with any mascon basin in particular (Figures 10 and 11), but, instead, they may be associated with previously identified cryptomaria that have been interpreted by previous workers to be the frozen remnants of lava-filled rifts and underlying feeder dikes (Miljkovic et al., 2015; Whitten and Head, 2015). We are not certain of the origin of the mafic intrusions, but our 30-km inversion models show that the roots of the mafic intrusions are connected to the zone of uplifted upper mantle beneath Oceanus Procellarum.

All four inversion models reveal important differences between Type I and Type II mascon basins. We found that Type I mascon basins show larger positive anomalies (>100

mGal) than Type II mascon basins (~60 mGal). We found that all Type I mascon basins share the following characteristics: (1) they contain larger and thicker impact melt sheet bodies than Type II mascon basins; (2) the crust below their impact melt sheets tends to be very thin (<6 km) compared to the crust below impact melt sheets in Type II mascon basins (~6-10 km); (3) they are associated with uplifted Moho at shallow depths (30-22 km); and (4) all Type I mascon basins are located within the boundary of Oceanus Procellarum. For Type II mascon basins, we found these common characteristics: (1) they have 25% thinner impact melt sheets than Type I mascon basins; (2) the crust below the impact melt sheet is thick (~6-10 km); (3) they do not always have an uplifted Moho at shallow depths (22-30 km); and (4) all Type II mascon basins are located outside Oceanus Procellarum.

We conclude that only very large impact events such as that which formed Mare Imbrium could trigger total crustal removal. For the Mascon basins that are smaller than Mare Imbrium, our model indicated that the bodies of lightly lower density than the average lunar crustal density still remain below the bodies of impact melt sheet. We speculated that large, mascon-forming impact events would have excavated the majority of the crust but not all of the crustal material and formed extensive impact melt sheets. Our modeling shows a maximum depth of melting of 16-25 km (depending on impact angle and impact velocity). Below the impact melt zone, we find a crustal density of 2,460 kg m^{-3}, which is lower density than the average feldspathic crust. This low-density crust indicates that the crust is highly porous and fractured, most likely due to impact brecciation. Underneath the crater floor is uplifted Moho. Our models suggest high-density zones of uplifted lunar Moho are also located at the thinnest part of mascon basins.

To validate the internal structure of Lunar Mascon basins obtained from our models, we compared our results to the well-known terrestrial impact basin, the Sudbury impact structure in

Ontario, Canada. We found that our model of lunar crustal structure and the structure of mascon basins is similar to the results of numerical modeling of the Sudbury impact structure in Ontario, Canada (i.e. Milkereit et al., 2010). The Sudbury impact structure differs from other known terrestrial impacts on Earth for its enormous size and features that more assimilate to impacts from other planetary system. The Sudbury impact structure including Chicxulub and Vredefort is one of the largest impact structures (> 250 km) on Earth. Only the Sudbury structure is hosting the remnant of solidified impact melt that overlays impact breccia and erosional relic of deformed multi ring impact basin (Riller, 2005; Pope et al., 2004). Another distinctive feature of the Sudbury impact structure is the fractured crater floor and associated dikes that are well preserved and can be seen in high-resolution topographic data (Milkereit et al., 2010). Because of the great thickness and mineralogic layering of the impact melt sheet, impact breccia, fractures crater floor similar to mineralogic layering of Lunar impact basin, the Sudbury impact structure can be used to identify with our lunar impact basin model. Our impact basin model suggests a different interpretation of lunar crustal structure and the structure of mascon basins than the model of Zuber et al. (2015). Comparing to the Sudbury impact structure, we found that our model provides mascon impact basin structure that resemble the structure of the Sudbury impact. We instead suggest that at least 8.9 km of brecciated crust remains between above the Moho beneath Mare Orientale similar to the Sudbury impact structure.

Previous gravity models of lunar impact basins suggested that most large impact basins completely excavated through the crust. For example, the gravity model of the Orientale basin at 3-5 km depth by Zuber et al. (2015) suggests a sharp transition between the basin floor and the uplifted Moho and implies that the basin-forming impact completely excavated the crust beneath Mare Orientale.

Based on our interpretations of Type I and Type 2 mascons, we conclude that variable styles of deformation occur as a result of large impact events, resulting in variable gravity anomaly signatures among major mascon basins. Both pre- and post-impact crustal structure and type greatly affect impact-induced deformation mechanisms of the mascon basins. In the early history of the Moon, the lunar farside crust may have been supported by a rigid lithosphere, whereas the lunar nearside crust (especially in Oceanus Procellarum and the PKT) may have been underlain by a molten KREEP-rich layer (Wieczorek and Phillips, 2000). The exponential rate of magma ocean crystallization indicates the KREEP-rich layer may have continued solidification and remained molten for an extra 200–400 million years or longer than the rest of the magma ocean (Wieczorek and Phillips, 1998; Wieczorek and Phillips, 2000; Nemchin et al., 2009). The age of KREEP-rich layer solidification were between 3.8 and 4.6 Gyr (Borg et al., 2004). Our suggestion is also supported by Mare Imbrium's weighted average age of impact at 3938 ± 4 Ma (Merle et al., 2014) that was older than the age of the KREEP-rich layer solidification. The coherence timing between the age of the KREEP-rich layer solidification and the timing of Mare Imbrium's impact indicates that Mare Imbrium's impactor may have hit the still molten KREEP rich layer and resulted in a complete removal of the brecciated crust as shown in our model.

The brittle deformation of the crust on lunar farside left behind a vast area of brecciated crust below impact melt sheets. The impact into the brittle target instead of the ductile flow regime could release more ejecta (Comerford, 1967). The negative density contrast between thick, brecciated crust, thick layer of loose ejecta, and the impact melt sheets can be seen as a negative ring in the bull's eyes gravity signatures typical of Type II mascons. In contrast, the impact onto the possibly ductile target on lunar near side, left behind only little to no brecciated

crust. The positive density contrast between thin brecciated crust, thin layer of loose ejecta, and thick impact melt sheets, and uplifted Moho can be seen as an extensive positive anomaly in the center of the bull's eyes gravity signatures typical of Type I mascons.

6. Conclusions

We performed power spectrum analysis on the GRAIL GL0660A lunar free-air gravity dataset and, for the major mascon basins on the Moon, we were able to quantify the size and thicknesses of impact melt sheets, the thickness and the density of crust below crater floors, and the elevation of uplifted lunar upper mantle. Our power spectrum analysis provides an understanding of lunar crustal structure, including the depth of prominent gravity signals and depth constraints for 2D gravity inversion models. Our power spectrum analysis results appear to be compatible with other lunar gravity studies (Zuber et al., 2015; Wieczorek and Phillips, 1998; Miljkovic et al., 2015; Andrews-Hanna et al., 2014). The low pass and preferential filtering approaches we use allow us to eliminate the high frequency gravity signal due to highly impacted subsurface from the total lunar free-air gravity anomaly. As a result, we are able to selectively perform inverse modeling on the gravity signal arising from features at a known depth and are also able to constrain the model with *a priori* knowledge from that depth.

Aside from the regional crustal structure that we are able to resolve, we are also able to model the detailed structure of several Type I (Mare Imbrium, Mare Serenitatis, Mare Crisium, Mare Nectaris, Humboldtianum) and Type II (Mare Orientale, and Moscoviense) mascon basins. Based on our model results, we suggest that the sources of the high gravity anomalies associated with mascon basins are: (1) impact melt sheets; (2) impact breccia; and (3) uplifted, shallow Moho. We conclude that the outer negative rings of the bull's-eye gravity signature of Type I mascons are due to low-density contrasts in the upper lithosphere. The upper lithosphere mainly consists of loose material ejected during the excavation stage of crater formation (Comerford, 1967). The high amplitude positive gravity anomaly (>60 mGal) of Type I mascon basins is directly influenced by the high density contrasts between shallow lunar mantle (3,220 kg m^{-3}),

very thin brecciated crust (2,460 kg m^{-3}), and moderate density impact melt sheets (2,770 kg m^{-3}), for example in Mare Imbrium and Mare Serenitatis (Figures 10 and 11, transect A-A'). The lower amplitude positive gravity anomaly (<50 mGal) of Type II mascon basins is directly influenced by thicker brecciated crust (2,460 kg m^{-3}) and a deeper Moho, both of which result in a reduced density contrast as seen in Mare Orientale and Moscoviense (Figures 10-11, transect A-A' and B-B').

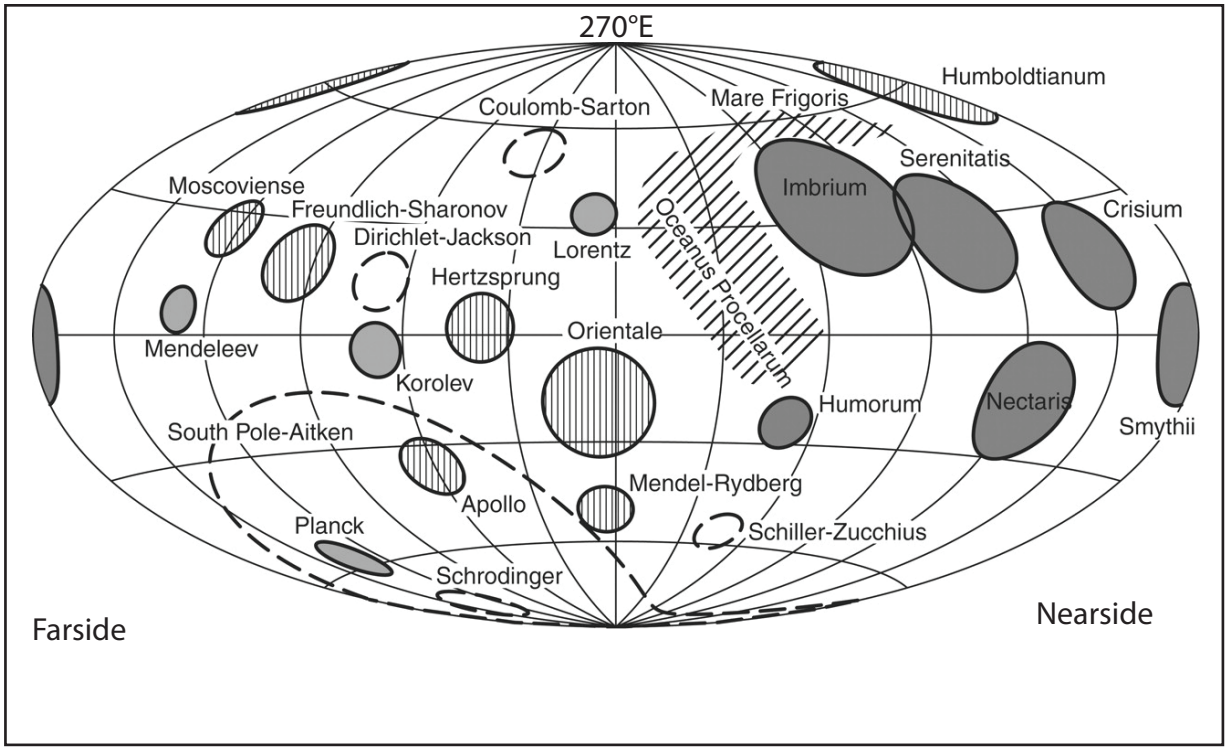

Figure 1. Locations of major lunar basins showed on the western side of the Moon viewed from Earth. The lunar nearside is to the right and the farside is to the left in this view. Dark shaded circles are Type I mascon basins which are Imbrium, Serenitatis, Crisium, Nectaris, Smythii, and Humorum. Hatched circles are Type II mascon basins which are Orientale, Hertzsprung, Moscoviense, Freundlich-Sharonov, Apollo, and Mendel-Rydberg. Circles with dashed lines are unclassified basins. Modified from Namiki et al. (2009).

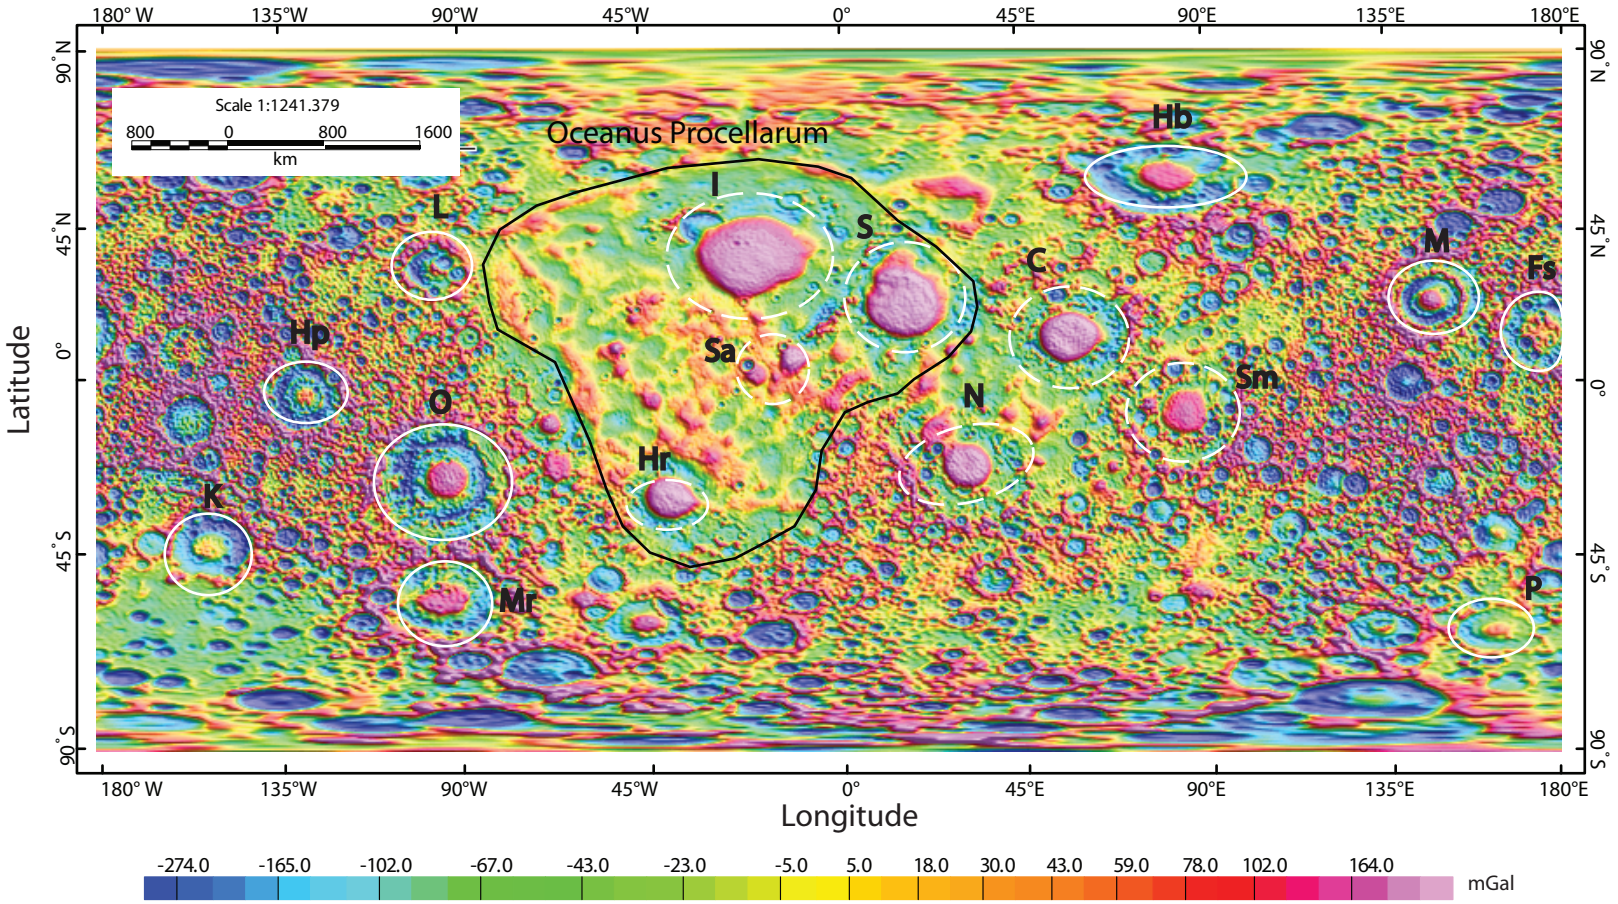

Figure 2. A GL0660A free-air gravity anomaly map. Dashed white circles are Type I mascons. Type I mascons show less prominent bull's eyes pattern and are located on Oceanus Procellarum (enclosed by black line) on the lunar nearside. Solid white circles are Type II mascons. Type II mascons show more prominent bull's eye surrounded with an annulus ring of negative anomaly. Type II mascons are located outside the Oceanus Procellarum (enclosed by black line) or on the lunar farside. I = Mare Imbrium, S = Mare Serenitatis, C = Mare Crisium, Hb = Humboldtianum, M = Moscoviense, O = Mare Orientale, Hr = Mare Humorum, N = Mare Nectaris, Mr = Mendel-Rydburg, Sm = Smythii, Fs = Freundlich-Sharonov, Hp = Hertzsprung, Sa = Sinus Aestuum, L = Lorentz, K = Korolev.

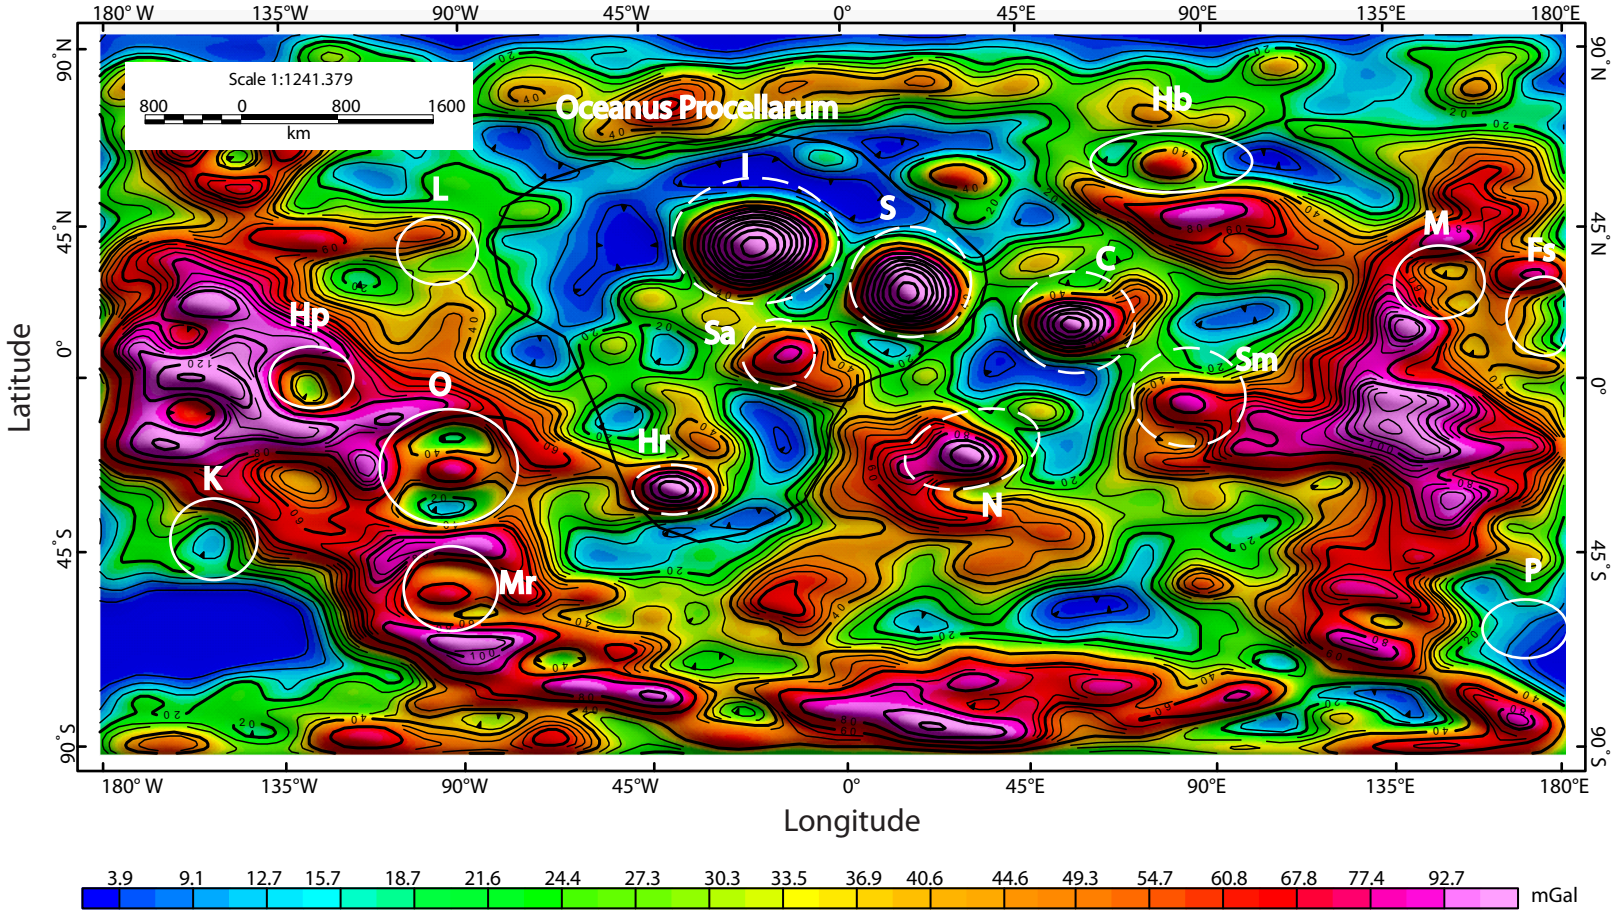

Figure 3. A low pass filtered GL0660A free-air gravity anomaly map. See Figure 2 for explanation of symbols and lettering.

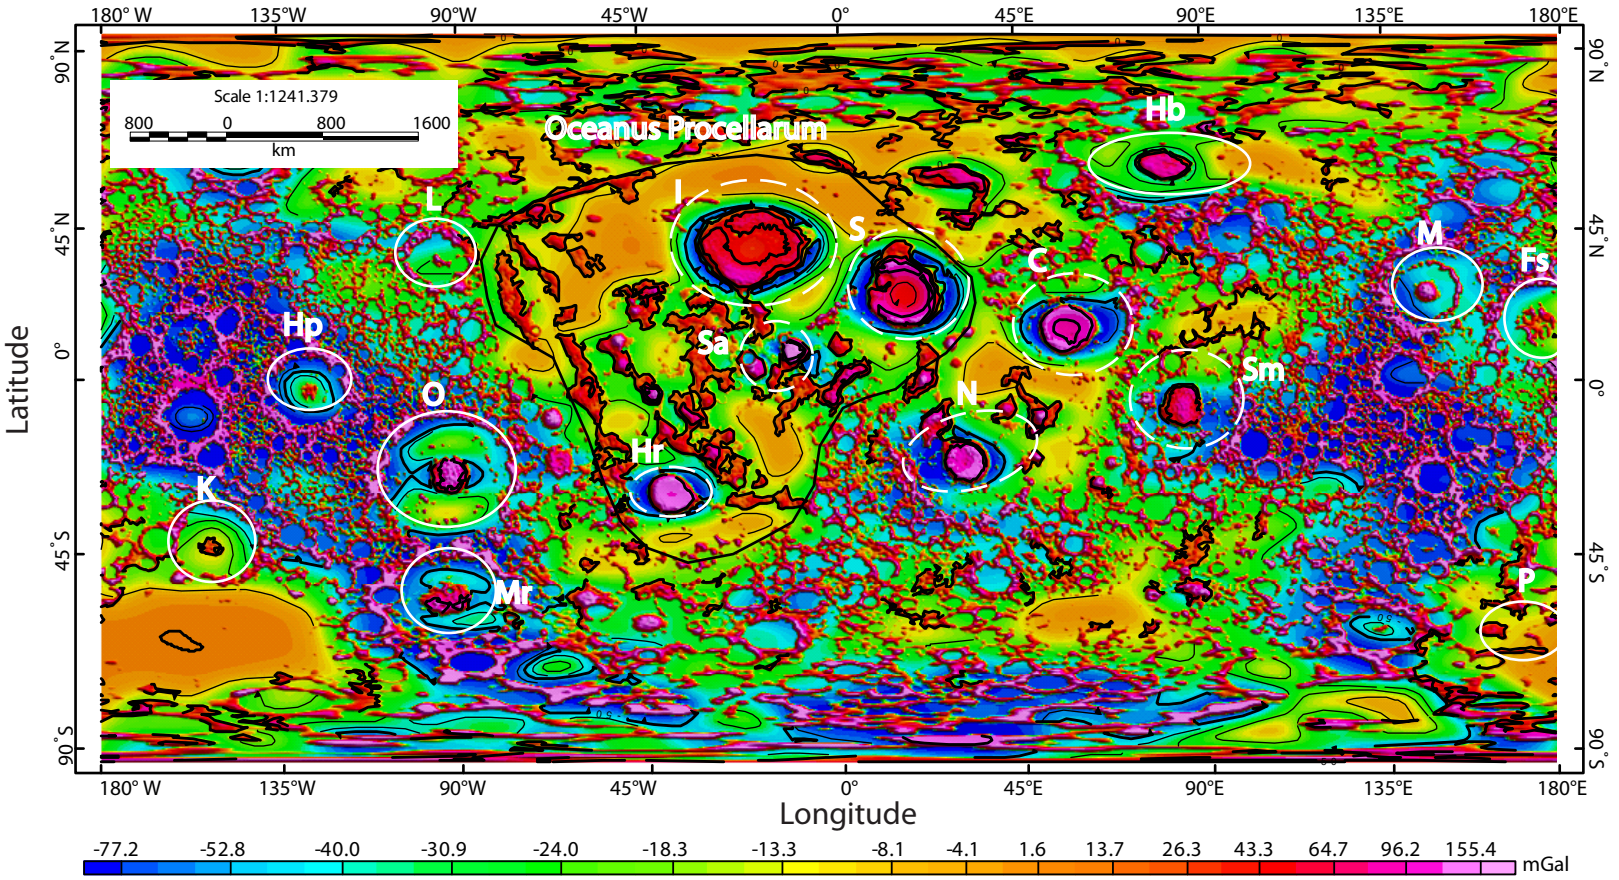

Figure 4. A high pass filtered GL0660A free-air gravity anomaly map. See Figure 2 for explanation of symbols and lettering.

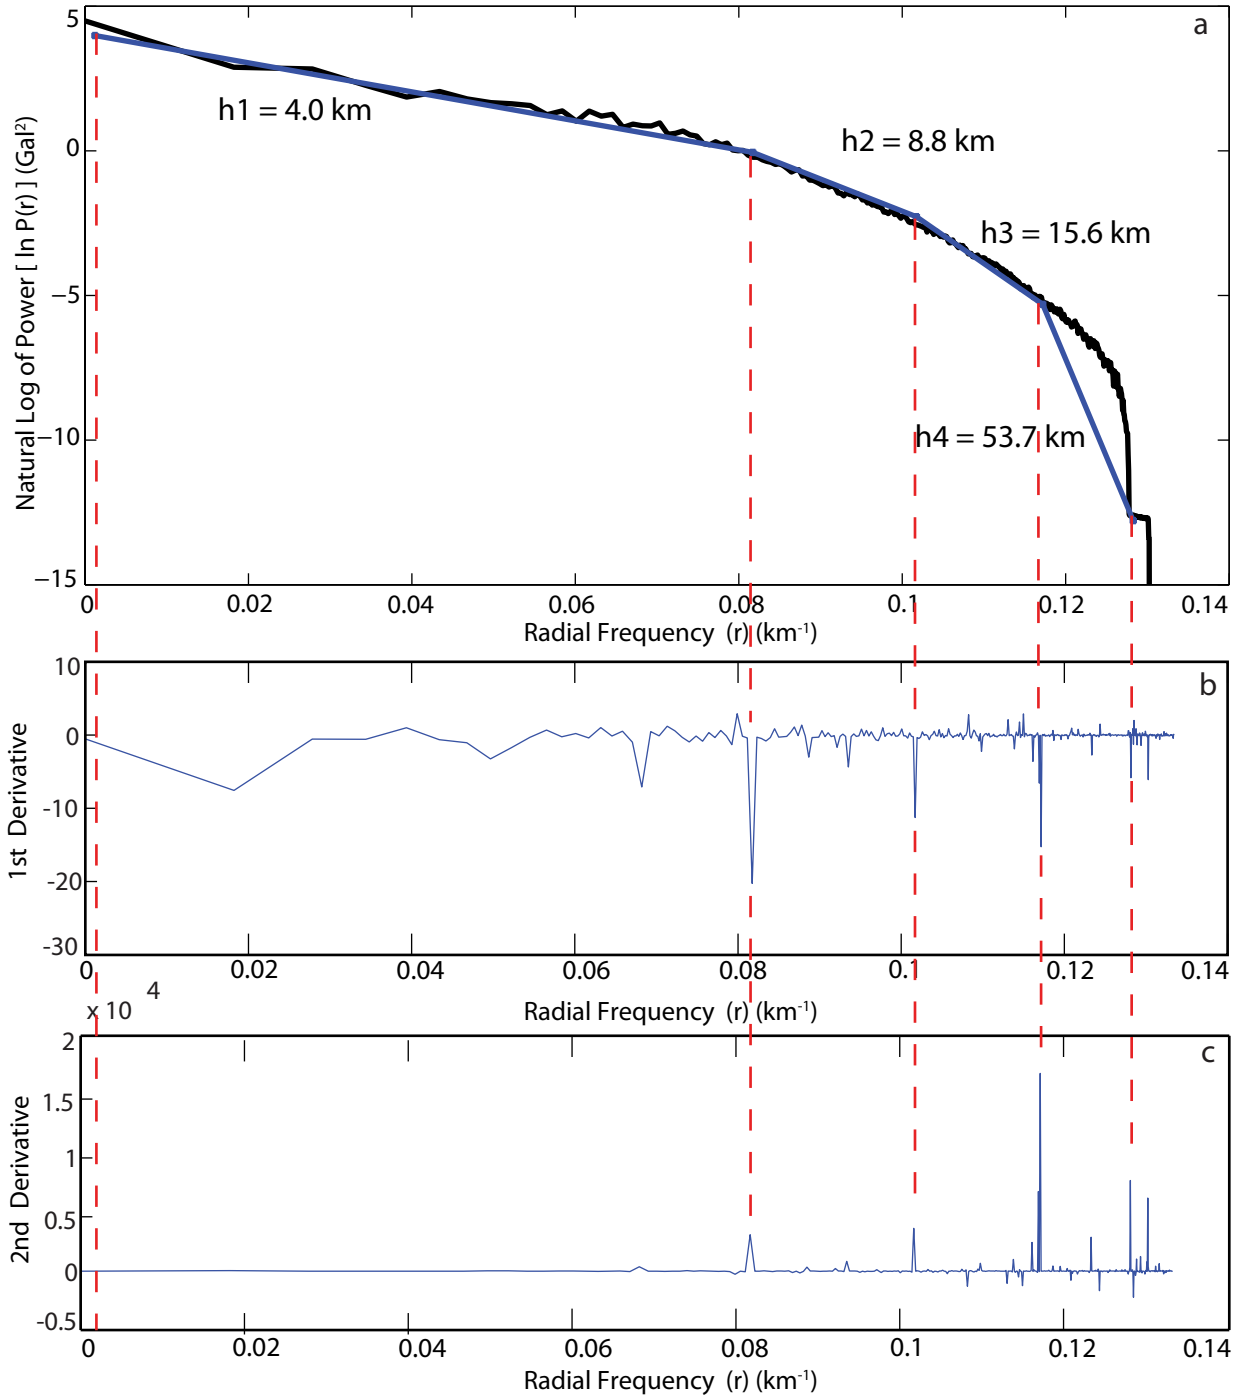

Figure 5. a) Power spectrum of the GL0660A free-air gravity anomaly map of the Moon. The x-axis is radial frequency of the gravity signal in the frequency domain. The y-axis is the natural logarithm of the power spectrum of the gravity signal. The black line is the spectrum of the gravity signal. Blue line segments represent ideal spectra fit to the lunar free-air gravity signal from different depths within the lunar crust. b) An alternate plot of the first derivative of the power spectrum show in a) and its radial frequency is used to define equivalence depths of the gravity signal. c) A plot of the second derivative of the power spectrum show in a). Red lines indicate the beginning and ending locations of each line segment.

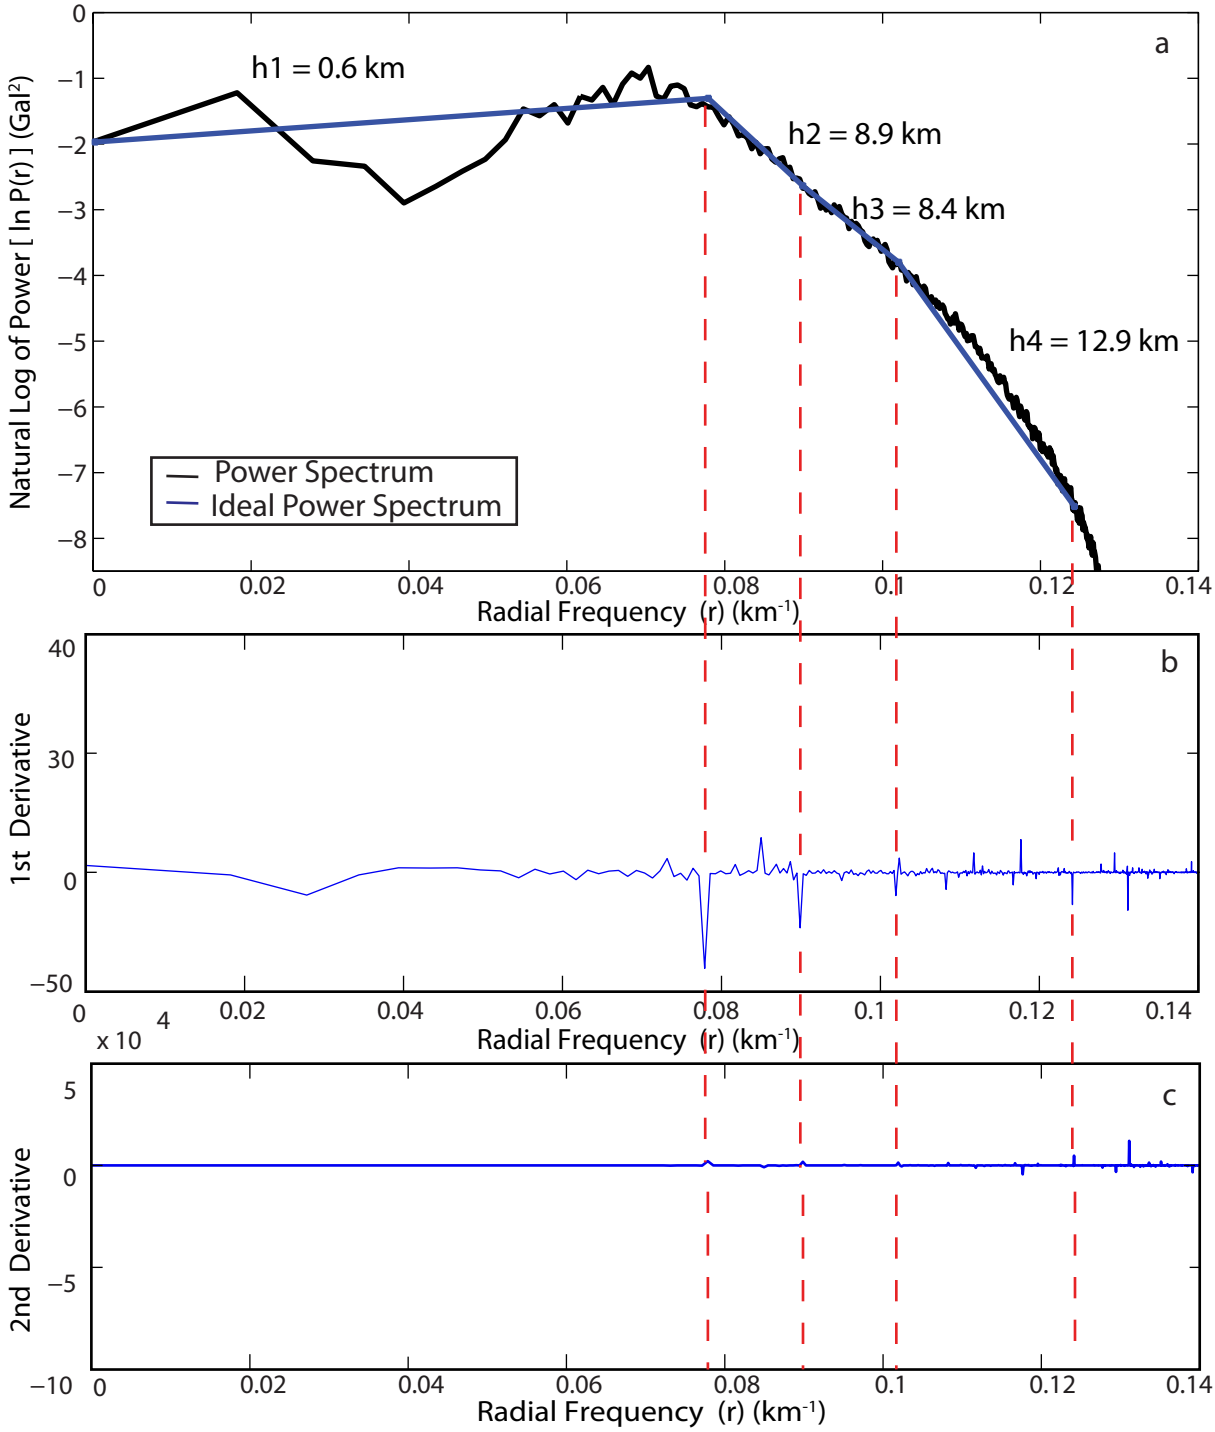

Figure 6. a) Power spectrum of the high-pass filtered GL0660A free-air gravity anomaly map of the Moon. The x-axis is radial frequency of the gravity signal in the frequency domain. The y-axis is the natural logarithm of the power spectrum of the gravity signal. The black line is the spectrum of the gravity signal. Blue line segments represent ideal spectra fit to the lunar free-air gravity signal from different depths within the lunar crust. b) An alternate plot of the first derivative of the power spectrum show in a) and its radial frequency is used to define equivalence depths of the gravity signal. c) A plot of the second derivative of the power spectrum show in a). Red lines indicate the beginning and ending locations of each line segment.

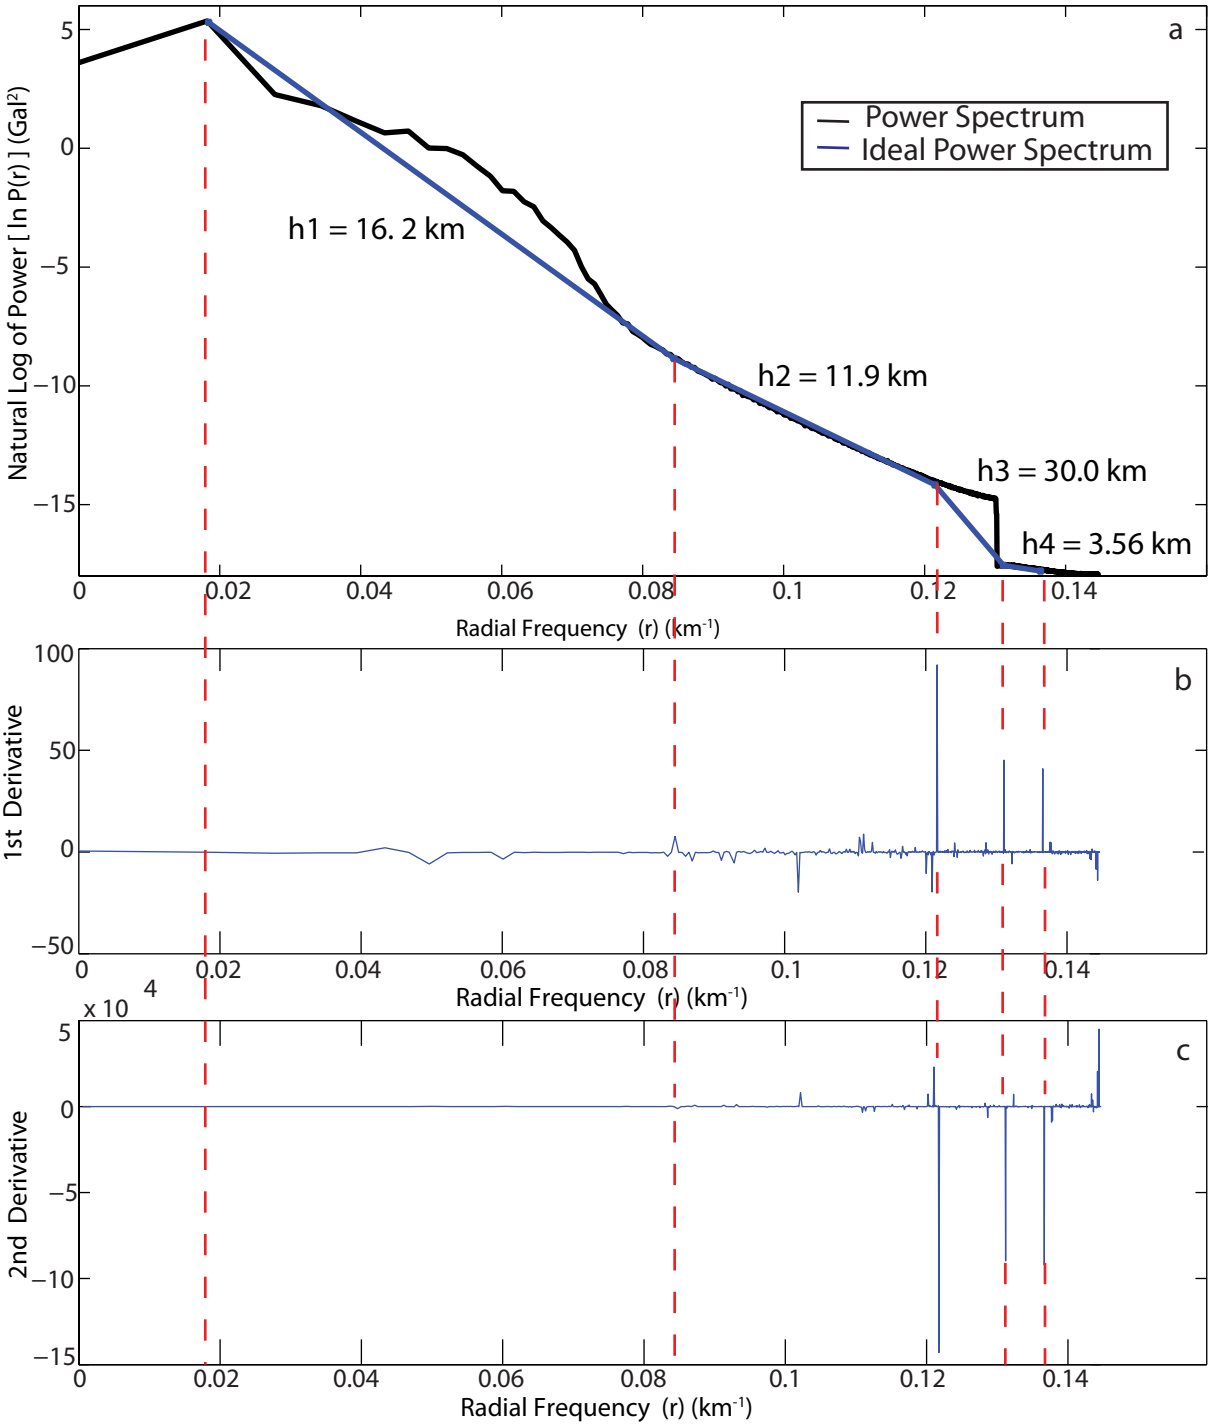

Figure 7. a) Power spectrum of the low-pass filtered GL0660A free-air gravity anomaly map of the Moon. The x-axis is radial frequency of the gravity signal in the frequency domain. The y-axis is the natural logarithm of the power spectrum of the gravity signal. The black line is the spectrum of the gravity signal. Blue line segments represent ideal spectra fit to the lunar free-air gravity signal from different depths within the lunar crust. b) An alternate plot of the first derivative of the power spectrum show in a) and its radial frequency is used to define equivalence depths of the gravity signal. c) A plot of the second derivative of the power spectrum show in a). Red lines indicate the beginning and ending locations of each line segment.

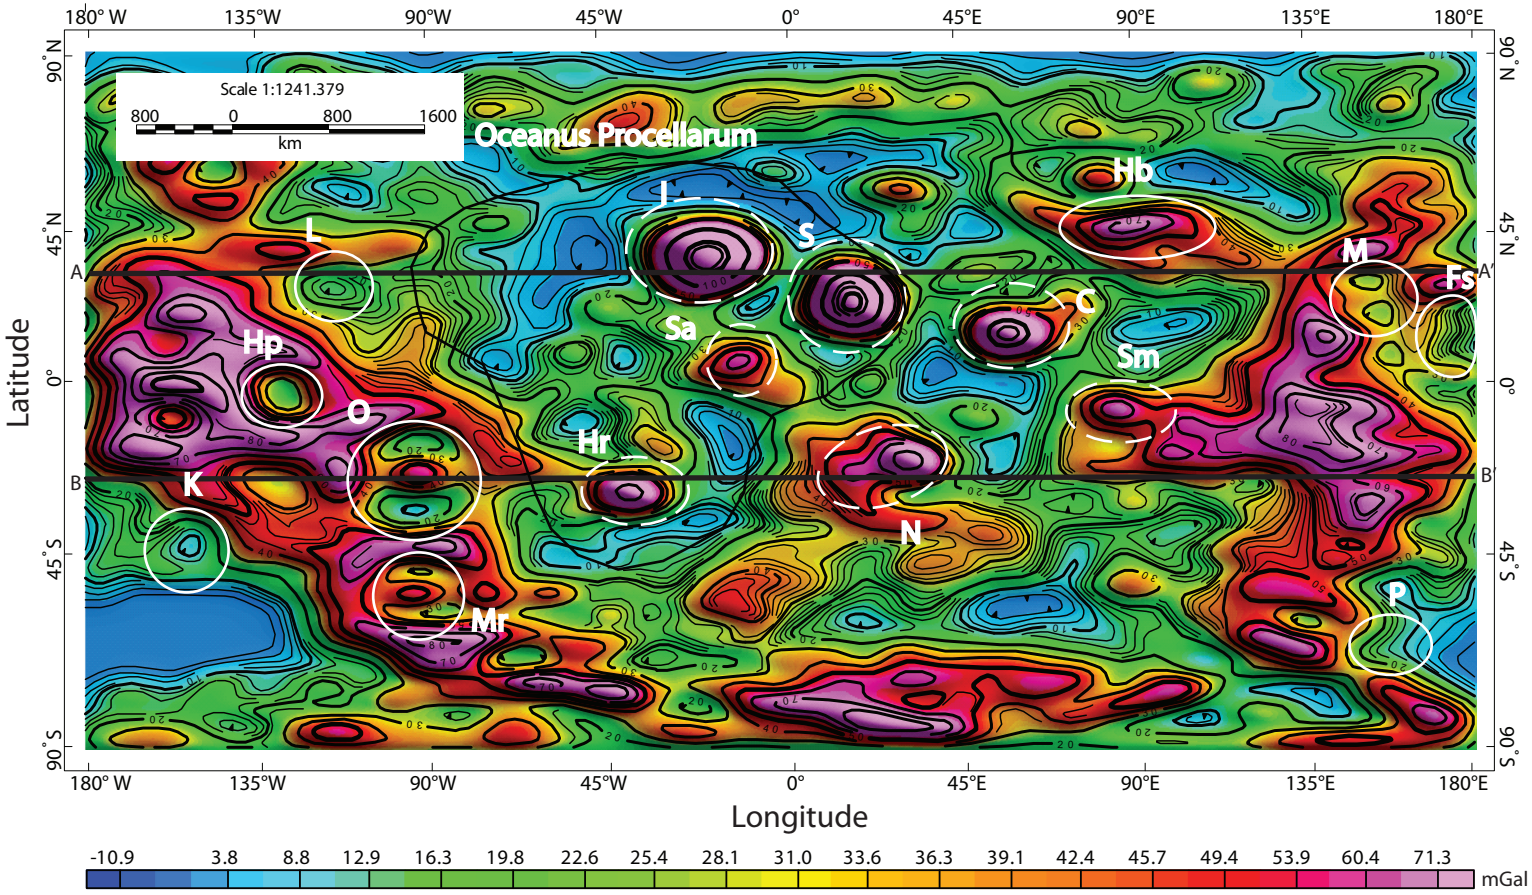

Figure 8. Contoured map of preferentially-filtered (16 km depth) and low pass filtered free air gravity anomaly GL0660A. See Figure 2 for explanation of symbols and lettering.

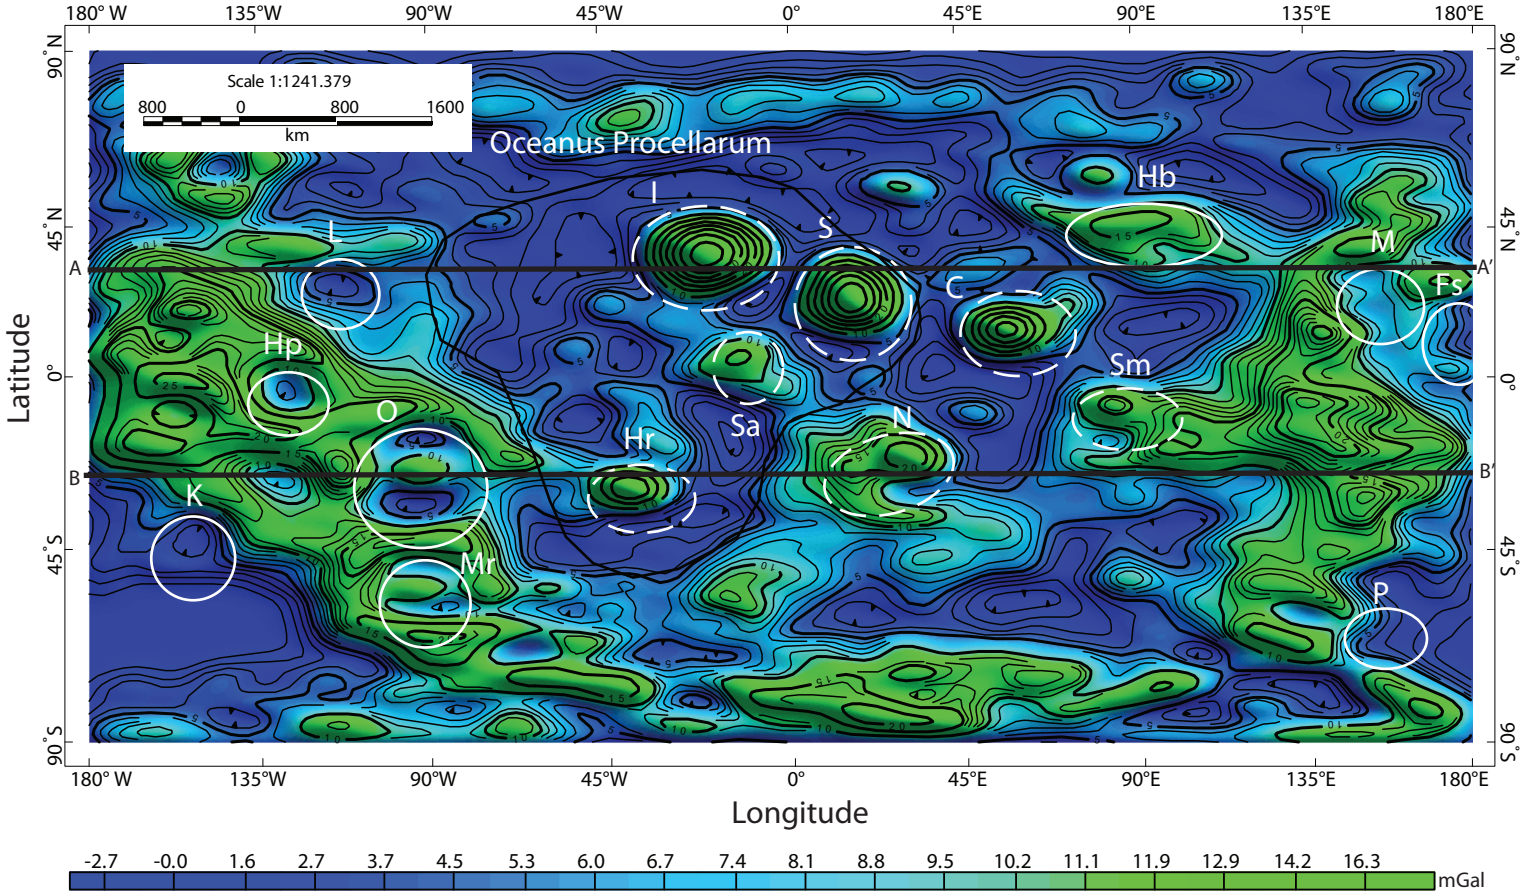

Figure 9. Contoured map of preferentially-filtered (30 km depth) and low pass filtered free air gravity anomaly GL0660A. See Figure 2 for explanation of symbols and lettering.

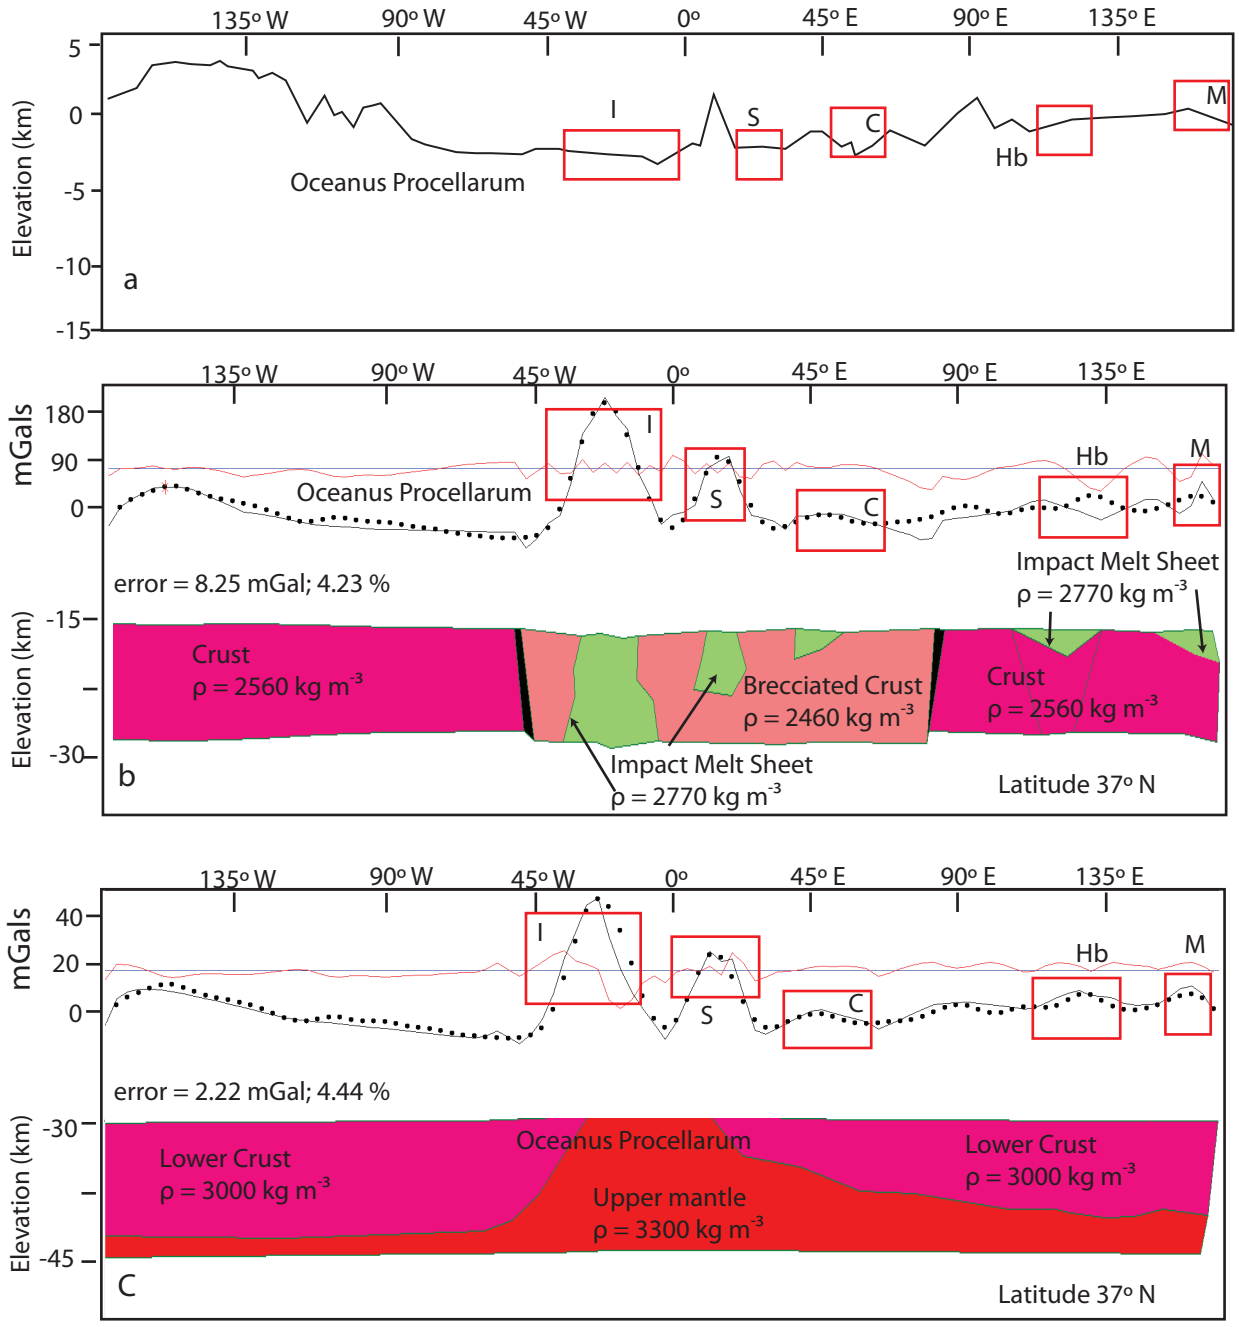

Figure 10. a) Black solid line is the topographic profile from Google Moon (2008). b) 2D inversion model of lunar crustal structure of a preferentially filtered and low passed filtered lunar free air gravity anomaly map GL0660A at a depth of 16 km at latitude 37°N [transect A-A' in Figure 8 and 9]. c) 2D inversion model of lunar crustal structure at a depth of 30 km at latitude 37°N [transect A-A' in Figure 8 and 9]. Dots are the observed, preferentially filtered gravity anomaly values. Dashed black line is the calculated gravity anomaly. Topography and crustal model are shown with 230x vertical exaggeration. Red line represents the misfit value between the observed and calculated gravity data. Red boxes are mascons; I = Mare Imbrium, S = Mare Serenitatis, C = Mare Crisium, Hb = Humboldtianum, M = Moscoviense.

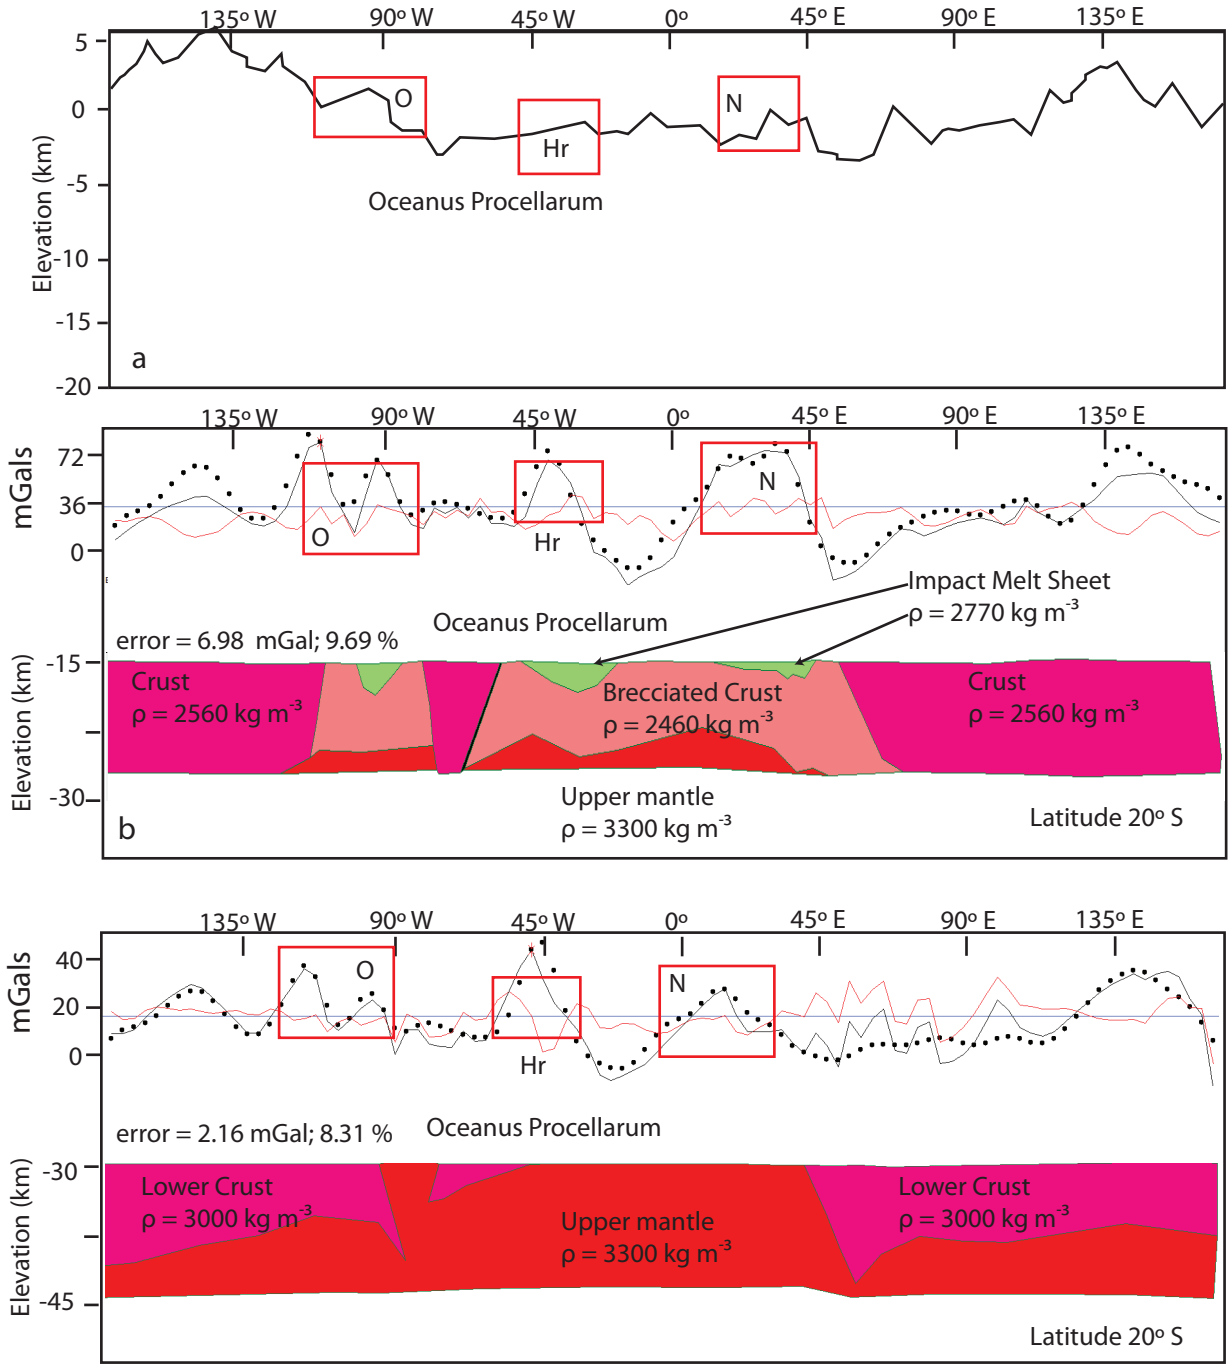

Figure 11. a) Black solid line is the topographic profile from Google Moon (2008). b) 2D inversion model of lunar crustal structure of a preferentially filtered and low passed filtered lunar free air gravity anomaly map GL0660A at a depth of 16 km along latitude 20°S [transect B-B' in Figure 8 and 9]. c) 2D inversion model of lunar crustal structure at a depth of 30 km at latitude 20°S [transect B-B' in Figure 8 and 9]. Dots are the observed, preferentially filtered gravity anomaly values. Dashed black line is the calculated gravity anomaly. Red line represents the misfit value between the observed and calculated gravity data. Red boxes are mascons; O = Mare Orientale, Hr = Mare Humorum, N = Mare Nectaris. Topography and crustal model are shown with 230x vertical exaggeration.

Appendix A: The Preferentially Filtering Routine for Gravity Signal

The routine of this code is based on the procedure suggested by Guo et al., 2013. This code is an adaptation of Guo et al., 2013 to separate the gravity anomaly of the Moon free air gravity signal-GL0600A. A detail explanation of this code can be found in Maksim et al., 2015. The input of this code must be a gravity or magnetic map in .csv (ASCII format). The output of the code routine will be 1) an interpolated plot of the original map, 2) a high pass filtered of the original map, 3) a low pass filtered of the original map, 4) am average radial power spectrum plot of selected map (unfiltered, low pass, or high pass), 5) option to make (x, y) selection on the power spectrum plot, 6) spectrum depths results from user's selection, 7) Five preferentially filtered maps from the selected depths, 8) an option to export all the maps product in .csv format to be further used for modeling. The code convert the input gravity or magnetic map from spatial domain to frequency domain. In frequency domain the code performs low pass and high pas s filtering then computes power spectrum of the low-pass signal and plots the average value of power spectral density to radial frequency or wave number. The code then generate an ideal power spectrum that will be used as a filtering operator to separate the interested band of spectrum from the rest of the data (Guo et al, 2013).

Chapter 5: Synthesis

I achieved the primary objective of this research, which is to design an integrated geophysical method for paleohydrogeological study with an implication in planetary exploration. The obtained product of the primary objective was the estimated quantity of the groundwater reservoir that fed the Kilbourne Hole eruption. I also achieved the second objective of this research, which is to develop a procedure to utilize the high-resolution lunar gravity data (GRAIL). The obtained product of the secondary objectives was two detailed crustal models of the Moon that reveal the internal structure of type I and type II mascons.

For the primary objectives, I performed my developed survey design on an analogous Earth site at Kilbourne Hole in New Mexico. As described in Chapters 2 and 3, I was able to successfully design ground-based surveys using GPR, gravity, and magnetics at Kilbourne Hole to map the internal structure of Kilbourne Hole. I am also able to further use the mapping result to quantitatively understanding paleohydrological conditions of Kilbourne at the time of eruption. The results show that these methods could be performed on Mars or the Moon. By integrating the result of my joint gravity and magnetic model and the GPR surveys at Kilbourne Hole, I yield quantitative constraints for the mass and volume of groundwater reservoir at the time of the eruption. In Chapter 2 I described in detail the method and results of gravity and magnetic survey and 2D gravity-magnetic joint inverse model. In chapter 3 I described in detail the method and results of my GPR surveys and volcanic blocks velocity analysis. However it must be noted that the gravity and magnetic surveys in Chapter 2 and the GPR surveys are not stand-alone results. To obtain the final product of this research which is the amount of groundwater in the reservoir at the time of Kilbourne Hole eruption, we must know the initial velocity of the gas expansion at the time of eruption which can only be retrieved from our GPR

results (Chapter 3) and we must know the mass of material that was excavated from the eruption, and the mass of magma which can only be retrieved from our gravity and magnetic result.

From the magnetic and gravity survey of Kilbourne Hole, NM described in Chapter 2, I mapped the extent and amount of erupted pyroclastic material. Inverse modeling of the gravity and magnetic data reveals three main basaltic dikes underneath Kilbourne Hole. The depth below the pre-eruption ground surface to the top of the dikes varies: dike 1, on the eastern rim of the crater, is between 1.75 to 2.25 km deep; dike 2, underneath the center of the crater, is between 0.91 to 3.58 km deep; and dike 3, underneath the western rim of the crater, is between 0.14 to 2.50 km deep. The three 2D magnetic and gravity jointed inverse models are also able to delineate several complex areas of slump and rotated blocks associated with crater collapse, the diatreme, and post-eruption fill units within the crater. The tuff ring deposit around the crater extends 600 m to 1 km away from the crater rim and my inverse models show that the tuff ring deposit varies in thickness and measures between 50 and 150 m. Based on the geophysical models I have developed for Kilbourne Hole, I estimate the mass of the magma (m_m) related to the Kilbourne Hole eruption to be $(1.38 \pm 0.15) \times 10^{13}$ kg and the mass of water (m_w) to be $(1.09 \pm 0.31) \times 10^{13}$ kg, for a water-to-magma mass ratio of 0.79 ± 0.23.

In Chapter 3, I show that a 250 MHz GPR can be performed on pyroclastic deposit in an arid, volcanic terrain at Kilbourne Hole to map the size distribution of volcanic blocks as a function of distance from the crater rim up to the depth of 2.54 m. Low-frequency (250 MHz) GPR surveys have the potential to probe the shallow subsurface to depths of 2.54 m in arid, volcanic terranes. Using the volcanic block size distribution, I estimate that the volcanic blocks were ejected during the Kilbourne Hole eruption at a velocity between 113-132 m s^{-1} and that the time duration of the gas expansion phase was as long as 81-103. s. The ejection velocity

suggests that the eruption occurred with an initial pressure of 163 ± 9 bar. Kilbourne Hole's maximum gas expansion and ejection velocity falls within the same ranges as other modern phretomagmatic eruption. Other workers observed recent phreatomagmatic eruptions to have the maximum gas expansion velocity to be between 100-400 m s^{-1}. The duration of the gas expansion phase is a good indicator about the groundwater reservoir that fed the eruption. The better the groundwater hydraulic flow, the longer the steam would continue to release. The initial pressure of the eruption is an implication to the depth of eruption center, depth of groundwater level, and the type of groundwater reservoir at the time of eruption. In the case of a phreatomagmatic eruption like Kilbourne Hole, the eruption originated at the contact zone between magma and groundwater reservoir. Therefor we can consider that the depth of eruption is roughly the paleo-groundwater level.

For the second objective of this research, I developed an additional method to the traditional gravity modeling to interpret the GRAIL data because even with the highest resolution (~7.6 km per pixel), it is still insufficient for studying the lunar subsurface as we do not presently have enough detail of lunar subsurface geology to constrain gravity models of the lunar subsurface. We performed power spectrum analysis on the GRAIL GL0660A lunar free-air gravity dataset and for the major mascon basins on the Moon. I show the detail on how to apply power spectra analysis, low-pass and preferential filtering, and 2D inverse modeling to interpret the Moon's complex crustal structure and to map the internal structure of Mascon basins in Chapter 4. We were able to quantify the size and thicknesses of impact melt sheets, the thickness and the density of crust below crater floors, and the elevation of uplifted lunar upper mantle. Our power spectrum analysis provides an understanding of lunar crustal structure, including the depth of prominent gravity signals and depth constraints for 2D gravity inversion

models. Our power spectrum analysis results appear to be compatible with other lunar gravity studies (Zuber et al., 2015; Wieczorek and Phillips, 1998; Miljkovic et al., 2015; Andrews-Hanna et al., 2014). The low pass and preferential filtering approaches we use allow us to eliminate the high frequency gravity signal due to highly impacted subsurface from the total lunar free-air gravity anomaly. As a result, we are able to selectively perform inverse modeling on the gravity signal arising from features at a known depth and are also able to constrain the model with *a priori* knowledge from that depth.

Chapter 4 provided a quantitative interpretation of the GRAIL data. Using the lunar free air gravity anomaly, we developed three filtered gravity anomaly maps and four 2-D inversion models that reveal the internal geologic structure of lunar mascon basins. Aside from the regional crustal structure that we are able to resolve, we are also able to model the detailed structure of several Type I (Mare Imbrium, Mare Serenitatis, Mare Crisium, Mare Nectaris, Humboldtianum) and Type II (Mare Orientale, and Moscoviense) mascon basins. We conclude that source of the high gravity anomalies associated with mascon basins are: (1) impact melt sheets; (2) impact breccia; and (3) uplifted, shallow Moho. We conclude that the outer negative rings of the bull's-eye gravity signature of Type I mascons are due to low-density contrasts in the upper lithosphere. The upper lithosphere mainly consists of loose material ejected during the excavation stage of crater formation (Comerford, 1967). The high amplitude positive gravity anomaly (>60 mGal) of Type I mascon basins is directly influenced by the high density contrasts between shallow lunar mantle (3,220 kg m^{-3}), very thin brecciated crust (2,460 kg m^{-3}), and moderate density impact melt sheets (2,770 kg m^{-3}). The lower amplitude positive gravity anomaly (<50 mGal) of Type II mascon basins is directly influenced by thicker brecciated crust

(2,460 kg m^{-3}) and a deeper Moho, which both result in a reduced density contrast as seen in Mare Orientale and Moscoviense.

To summarize the accomplishment of my research for this dissertation, the results from my study at Kilbourne Hole not only validate the ability of my method in planetary exploration, but it also reveals important information about the internal structure of Kilbourne Hole, its eruption history, and the paleo-hydrologic conditions of the Rio Grande rift basin in much more detail than any surface geological study could. We had demonstrated that our research from Chapter 2 and 3 could serve as a pilot study as an implication for planetary geophysical surveys to understand hydrogeological history of a planet such as Mars. The results of a GPR survey similar to the one performed at Kilbourne Hole could be used to map the size distribution of volcanic blocks at a phreatomagmatic volcano on Mars from which an estimate for the amount of groundwater involved in the eruption could be made. I also introduce in this research an application of low pass filtering, radial power spectrum depth analysis (Spector and Grant, 1970), and preferential (Guo et al., 2003). These additional techniques helped us find a way to constrained and increase reliability of the obtained gravity models that reflect the internal structure of the Moon, even with minimal *a priori* knowledge of the Moon's complex geology. My models successfully provided quantitative interpretation of mascon basins and crustal structure of the Moon. The application of our integrated geophysical method also provided us geophysical model of Kilbourne Hole that are more reliable than solely using the geophysical modeling method with limited *a priori* data.

In conclusion, GPR, gravity, and magnetic surveys are low cost, provide data that are easy to process, and the fieldwork can be quickly conducted. Data collection and interpretation can be done within days or weeks, and can provide preliminary information instantly at the time

of data collection. With appropriate data processing (dependant on geological setting and field conditions: see detail in chapter 2 and 3), we can later derive quantitative interpretation from the data. To design surveys and data processing on Mars, we need to base the survey design on the electrical properties of Martian volcanic material, possibly on the analog material or from other context. As of now there are several studies on a dry regolith unit and two volcanic ash units in Elysium Planitia that yield high electrical permittivity (6 F/m) and low attenuation constant (~30-50 dB) (Picardi et al., 2004; Heggy et al., 2006: Vaucher et al., 2009). These preliminary conditions of Martian volcanic material is somewhat compatible with the volcanic material at Kilbourne Hole and may allow low frequency radar signals to propagate to greater depths.

The future recommendations to improve and to carry on our research in addition to other workers' numerous research (Picardi et al., 2004; Seu et al., 2007; Hamran et al., Kobayashi et al., 2014; 2015) involving the design and test of geophysical instruments for Mars and the Moon are: 1) utilize several types of GPR, gravimetry, and magnetometry equipment that have been deployed at Mars and the Moon (Seu et al., 2007; Hamran et al., 2015) to conduct a ground based GPR, gravity and magnetic survey similar to what I am doing at Kilbourne Hole, 2) to practical adaptations of our method for Martian ground based surveys as well as a number of other key observations must also be made to retrieve better quality *a priori* information of Mars and Moon rock. In addition to present exploration of Mars that is focused on evaluating the habitability of surface environments, we argue that we may also need to look back further in time as the Martian surface had become extremely cold, oxidized and arid long before. With further observations, great information can be learned about the climate history of the terrestrial planets through this type of research. For a lunar and Mars mission, my gravity and magnetic surveys would provide us with a richer data set than the current high-resolution free air gravity anomaly

map from GRAIL. I am excited for the next decades and for the possibility that I may soon be able to apply my methods to exploring the surfaces of Mars and the Moon.

Curriculum Vitae

Nisa Maksim is a granddaughter of a corn farmer. She was born and raised in the rain forest of rural Thailand. She received her Bachelor of Science in Physics from Kasetsart University in 2004 and a Master of Science in Geophysics/Hydrogeology in 2006 from Chiang Mai University. She had spent some years working and digging as a paleontologist in Southern California. She later decided to go back to school and pursue her doctorate education and got accepted to the doctoral program with the Department of Geological Science at the University of Texas at El Paso in 2011. Her dissertation title is an Integrated Geophysical Surveys at Kilbourne Hole, Southern New Mexico: Implications for Near Surface Geophysical Exploration of Mars and the Moon. Dr. Jose M. Hurtado Jr. is her supervisor. Nisa Maksim was the recipient of several scholarships and awards including a UTEP-NSF GK12 fellowship, UTEP-LEAP grants, Chevron's Students Leaderships Symposium Award and Dodson's Research Award. Nisa Maksim dedicated her times at UTEP to both inside and outside curriculum activities. She had served as the 26th UTEP Geology Colloquium co-chair and had served as a vice president and a president to the Society of Exploration Geophysicists (SEG)-UTEP student chapter in 2012-2014. She had been travelling the world to participate in numerous international meetings and to climb several mountains from India to the middle of nowhere in Mexico and Mount McKinley. Nisa Maksim received her doctoral degree in the summer of 2016. After graduation Dr. Maksim will follow her military husband to Wiesbaden, Germany and hopes to receive a post-doctoral fellowship to continue doing her research over there. If not, as a geologist and an army wife, she will probably find some other dirt/rock related jobs to do.
