ACKNOWLEDGMENTS

Thank yous are extended to:

Richard Langford for recommending the topic, assisting with field work, assistance with the computer maps. Without his direction, I would still be writing.

Tom Gill for serving as sounding board, alerting me to upcoming deadlines, and for being the final set of "fresh eyes" to do proof read the work..

Terry Pavlis and Richard Jarvis for proof-reading and alerting me to areas that needed clarification.

Robert C. Trentham for serving on a second of my graduate committies. In spite of being 300 miles away, he had major input in the content. Without Dr. Trentham' help while I worked toward the BS and MS, I would not have had the background to attempt this effort..

Carlos Montana for last minute help with the gravity data relating to the Sacramento, San Andres, and Guadalupe Mountains.

Franklin State Park and the Bowen Ranch gave permission to access the areas of interest.

Robert F. Lindsay for directing me to the terraces near Guadalupe Peak.

Stephanie Ray who was my field assistant. Scheduling made her more a proof reader and a questioner who forced me to think through what I was writing.

James W. Granath agreed to be one of my referees, and H. Jay Melosh clarified sections of his quoted effort. Their structural and geomorphology classes taken nearly 35 years ago provided me with a good foundation in geology. Both have answered innumerable questions in the intervening years.

Daughter Marcia taught me how to use Excel's graphing capabilities, answered statistical questions, then proofread the final drafts.

Daughter Glenda took care of my home in Midland, looked for books and whatever else was at "the wrong house". They tolerated my early geology and leveling classes when they were in grade school and would really rather have had me paying attention to their wishes.

Marcia Beth Couch, Robin O'Connor, and Michael Sorensen, consistently served as sounding boards and generally offered general technical support.

And maybe I should thank my friends in Midland who asked every time I was in town
"When will you finish and come home?"

ABSTRACT

This study examines Basin and Range topography relating tectonic processes to topographic features. The observation that the terraces along either side of the Franklin Mountains were deformed and uplifted is a reflection of tectonic uplift. The uplift represents long-term deformation of the range. This led to the question of what shapes the deformation and does it represent differential subsidence into the Rio Grande Rift or true uplift. A more regional study of the Sacramento, San Andres, and Guadalupe Mountains follows. Two papers form this dissertation.

The Río Grande Rift and the Franklin Mountains, in particular, are the subject of the second chapter. The indication for tectonic uplift is the terraces along the flanks of the Franklin Mountains mimicking the curve along the crest of the range.

In light of the results from the Franklin Mountains, Chapter three examines the Sacramento, San Andres, and Guadalupe Mountains. Location data were converted to UTM Zone 13 measurements then long-wavelength elevation changes were modeled by use of transects drawn from digital elevation models (DEM) at 15 minute intervals between the Pecos River of eastern New Mexico across to Arizona on the west. A 2nd order polynomial was fit across the transects then a map was constructed based on the polynomials. The three modeled ranges are among those that show uplift above the smoothed surface. Furthermore, the ranges all exhibit arcuate crests implying a similar origin. A gravity map between 31° N, -104° W and 35° N, -110° W was multiplied by the inverse of elevation to emphasize the correlation between elevation and subsidence into the rift basins.

CHAPTER 1: INTRODUCTION

This study examines the Basin and Range province topography and relates it to local tectonism. The Franklin Mountains are flanked by terraces that have been deformed. Their uplift represents long-term deformation of the range. This led to the question of what was the shape of the deformation, and whether it represented differential subsidence or true uplift. The study expanded to a more regional study that included the Sacramento and Guadalupe Mountains and then to the Basin and Range as a whole. Two papers, comprising Chapters 2 and 3 resulted from this research.

The Chapter 2 investigates the Río Grande Rift and the Franklin Mountains. Terraces were mapped using a high resolution GPS to determine the elevations of the highest terraces underlain by basin-floor sediment. Uplift of the Franklin Mountains was demonstrated by a topographic profile of terraces that on the east and west flanks mimicking the crest of the range is indication of tectonic uplift.

Chapter 3 compares the Guadalupe, San Andres, and Sacramento Mountains in light of the results from the Franklin Mountains. First, a gravity map that combines gravity with topography was created. Digital elevation models (DEM) were profiled at 15 minute intervals between latitude 31 and 35, between longitudes 104 and 110 west. A second degree polynomial was fit to the transcripts and a smoothed surface was constructed. This was related to the uplift history of the ranges and to the evidence of tectonic uplift versus differential subsidence was discussed.

CHAPTER 2: LONG-TERM DEFORMATION IN THE SOUTHERN RÍO GRANDE RIFT AS INFERRED FROM TOPOGRAPHY AND UPLIFTED TERRACES

ABSTRACT: The long-term deformation of the Franklin Mountains in the Río Grande Rift was estimated by measuring the elevation of Late Pliocene terraces that line the footwalls of the range-front faults. In most extensional terrains, alluvial fans and bajadas cover faults and terraces thus making documentation of long term uplift difficult. However, rapid aggradation of the basin floors by extensive playa lakes and floodplain deposits of the Río Grande river buried the irregular mountain front fans creating the low-gradient surface. Subsequent faulting deformed and uplifted the low-gradient surface, revealing the long-term deformation of the mountains.

The uplifted terraces are exposed along both sides of the Franklin Mountains and along the east side of the Sierra Robledo in south central New Mexico. In the Franklin Mountains, the terraces lie 130 m above a younger surface, indicating that this is the minimum amount of uplift. The profile of the anticline parallels the profile of the range crest of the mountains. Three important conclusions can be drawn from uplift of the terraces. First, the observation that the terraces parallel the range crest implies that the topography of the mountains is tectonic in origin and that there was a low relief surface prior to deformation. Second, the east side terraces are higher than the west side terraces, showing rotation of the mountains during deformation, and providing an estimate of the percentage of deformation recorded by the terraces at about five percent of the total rotation. Third, the open arch correlates points to differential slip on the fault plane as a factor in the uplift.

Two models for causing the differential slip associated with apparent uplift are 1) differential subsidence that results in the denudation of the horst blocks that are subsiding less rapidly and 2) true uplift, related to flexural deformation along with the fault plane and mid-crustal flow rotate the Franklin Mountains block.

INTRODUCTION

This paper documents and discusses the uplift of Pliocene terraces surrounding the Franklin Mountains within the southern Río Grande Rift, in far west Texas and south central New Mexico and reveals the shape of long-term extensional uplift of the terraces. The terraces along the slopes of the mountains are composed of the Fort Hancock and the Camp Rice Formations, part of the Santa Fe Group; deposition of these formations took place between 20 and 2 Ma (Gile and others, 1981; Collins and Raney, 1991)

REGIONAL SETTING

The Franklin Mountains extend from the City of El Paso, Texas on the south end into southern New Mexico (Figure 2.1). The range trends north-south and exposes Precambrian granite and metavolcanic rocks overlain by Paleozoic strata. Uplift of the mountains tilted the strata so the mountains presently dip westward at angles 40 to 80 degrees (Harbour, 1972).

The Franklin Mountains are an uplift associated with the Río Grande Rift. There are nine basins and 16 sub-basins within the Río Grande Rift (Mack and others, 1997) (Figure 2.1, Figure 2.2, and Figure 2.3). The majority of the basins of the Río Grande

Rift are half grabens that alternate orientation along the rift (Mack and Seager, 1990). Chapin and Cather (1994) propose accommodation zones as the links between the west-tilted and east-tilted basins. Figure 2.1 shows the accommodation zones that lie along the small circles of an Euler Pole in eastern Utah (Chapin and Cather, 1994).

The Tularosa and Hueco Basins combine to form a basin nearly 300 km (Figure 2.1). The Mesilla Basin is approximately 35 km wide by 100 km long. The Mesilla Basin, on the west side of the Franklin Mountains, is distinguished from the Los Muertos Basin in Mexico by a “poorly defined ground-water divide” (Hawley and Lozinsky, 1992). Mack and others (1997) also consider the Mimbres Basin west of the Mesilla Basin to be part of the Río Grande Rift. The total width of the Mimbres, Mesilla, and Orogrande Basins spans approximately 100 km.

Beginning in the Miocene, the Río Grande carried sediment from the mountains of Colorado and northern New Mexico modifying the landscape in ways important to this study. The southern part of the rift was the depositional center of this extended axial stream system and pre-existing topography was largely buried under rapidly aggrading fluvial and lacustrine sediments.

The first evidence of the Rio Grande in the southern rift near the Franklin Mountains has been dated at five Ma by using paleomagnetic reversals and dating of volcanic rocks interbedded within the sediments (Mack and others, 1998). Fluvial deposition shifted to the east side of the Franklin Mountains by two million years ago when the ancestral Rio Grande spilled through Fillmore Pass between the Organ and Franklin Mountains (Hawley and others, 1969). By the early Quaternary (2 Ma), the ancestral Rio Grande had spilled through Fillmore Pass between the Organ and

Figure 2.1 Index map (modified from Keller and Cather, 1994) of the Río Grande Rift with accommodation zones (adapted from Chapin and Cather, 1994) shown as parallel lines and traditional dip symbols displayed in the asymmetric grabens. The two areas of interest are in black. Basin bounding mountains (adapted from Armstrong and others, 2013) are: D-Davis, A-Apache, De-Delaware, G-Guadalupe, S-Sacramento, O-Organ, SAu-San Augustine, SAn-San Andres, Sa-Sandia, SC-Sangre de Cristo, F-Front Range.

Figure 2.2. Map showing the collected points with relation to mountain. Not all points were used-higher points were replaced with lower points to avoid the influence of the alluvial fans.

Figure 2.3. Cross-section showing the general location and elevations of the major peaks and gaps in the Franklin Mountains.

Franklin Mountains and was filling the Hueco Basin with river sediments (Hawley and others, 1969).

Deposition on the basin floors ended about 700,000 years ago (Vanderhill 1986; Mack and others, 1993; Hawley and others, 1969; Mack and others 1998; Lucas and others 1999; Gile 2007). The 640,000 year old Lava Creek Ash B is found in the oldest sediments inset into the top of the valley in Selden Canyon and El Paso Narrows, demonstrating that initial Mesilla Valley down-cutting occurred before 650,000 years ago (Izett and Wilcox, 1982; Seager and others 1984; Gile and others 1981 and 1995). The final depositional surface forms the lower La Mesa surface (Gile and others, 1981), a broad flat slope that dips southward at approximately 0.001 meter per kilometer.

FRANKLIN MOUNTAINS and EAST FRANKLIN FAULT ZONE

The Franklin Mountains are separated from the Hueco Basin to the east by the East Franklin Fault Zone. On the west, a complex of faults known as the West Franklin Fault Zone and the Mesilla Valley Fault separate the range from the Mesilla Basin (Lovejoy, 1971), (Figure 2.2). The range is cross-cut by several northwest and west trending normal faults (Lovejoy, 1975; Collins and Raney, 1991). None of these faults offsets the range-bounding faults so their movement must have ceased prior to the deposition of covering basin fill (Scharman, 2006).

The Hueco Basin (Figure 2.1) is more than 170 km long and 50 km wide, approaching three km deep near the east side of the Franklin Mountains (Collins and Raney, 1997; Averill and Miller, 2013). Numerous Quaternary faults cut the surface of

the Hueco Basin (Collins and Raney, 1994), (Figure 2.4). The fill is a combination of alluvium and Fort Hancock Formation sediments dating from 20 Ma (Gile and others, 1981; Collins and Raney, 1991) covered initially by Camp Rice Formation. Since 700,000 years ago, the basin has been weakly eroded and covered by alluvium and sand dunes.

Ramberg and others (1978) show an echelon faulting along the east side of the Franklin-Organ-St. Augustine-San Andres chain. Their data do not contain sufficient detail to distinguish small fault segments. They estimated 9.6 m of Holocene to late Quaternary slip based on a fault scarp 35 m long on the east side of North Franklin Mountain and about seven meters of slip near the south end of the Franklin Mountains.

The East Franklin Fault is the more active of the boundary faults. Studies near White Sands Missile Range indicate the last movements on the East Franklin-Organ Fault Zone occurred within the last 4000 to 5000 years (Seager, 1980). The date was determined by comparing soil development on the oldest unfaulted fan to the soil on the youngest faulted fan (Seager, 1983). Movement along the Artillery Range Fault section of the East Franklin Fault Zone may have blocked the ancestral Río Grande's course into the Hueco Basin (Mack and others, 2006).

A study of the East Franklin Mountain Fault Zone by McCalpin (2006) focused on a trench a few meters south of Hitt Canyon within three km south of the Texas-New Mexico state line (Figure 2.2). McCalpin found five normal faults, though there was uncertainty associated with the older faults. He was able to date three slip episodes using ^{14}C and compared them with infrared-simulated luminescence done on four fine, inorganic silt samples. The mean throw was 3.5 m although two paleoearthquakes

Figure 2.4. Cross-section through Munday Gap area showing two boundary faults across the Franklin Mountains plus the faults within the Hueco Basin.

exhibited displacement of about three meters. A mean slip rate of 0.175 mm/yr was estimated as a minimum slip rate from the last 16,400 years from the total displacement of 11.2 meters.

WEST BOUNDARY FAULT ZONE and MESILLA BASIN

There are differing interpretations of the West Franklin Fault Zone. Lovejoy (1975) proposed that this fault extends the entire length of the Franklin Mountains and possibly as far north as along the west side of the Organ, San Augustin, and San Andres ranges (Figure 2.1), though he believed it is partially covered by possible landslides especially along the Franklin Mountains. Harbour (1972) saw no evidence of this fault north of Avispa Canyon (Figure 2.2). There are no conspicuous offsets of the Pliocene terraces along the fault trace indicating the fault is no longer active or has a very long interval between seismic episodes.

Scharman (2006) pointed out that there are many low angle normal faults associated with the Franklin Mountains and other ranges along the Río Grande Rift. Based on the angle the low-angle faults cross bedding plains, Scharman (2006) supported Seager's (1980) hypothesis that the low-angle faults originally were high angle normal faults rotated during uplift and extension and are older than the range-bounding faults.

The Western Boundary Fault Zone cuts a major thrust fault and numerous smaller faults so this fault is strictly of Basin and Range origin and not a reactivation of previous deformations (Scharman, 2006). The fault boundaries of the Franklin Mountain structure are curved in map view; this may be due to irregularities within the

basement rocks (Harbour, 1972; Collins, 1996).

The West Franklin Fault Zone appears to be inactive because nowhere does it disrupt the terraces (Scharman, 2006). The active major fault along the western side of the Franklin Mountains is the Mesilla Valley Fault (Henry and others, 1985) (Figure 2.2). This fault is between Interstate 10, a kilometer or more west of the mountains, and the Río Grande still farther west. It may extend north to Las Cruces where it merges with similar faults between the Doña Ana and East Robledo Faults (Lovejoy, 1975). Gravity and magnetic data between the West Franklin Fault Zone and the Mesilla Valley Fault suggest there are three smaller, stair-step faults under valley fill (Imana, 2003).

SEDIMENTARY RECORD

Basin fill has buried the bedrock of all but the Franklin and Juarez Mountains (Hawley and Lozinsky, 1992). The sedimentary record of the Río Grande rift system includes Miocene strata and the Plio-Pleistocene Fort Hancock and Camp Rice Formations of the Santa Fe Group (Hawley, 1975; Mack and others, 1998), (Figure 2.5). The Fort Hancock Formation is composed of playa, lacustrine, and alluvial fan facies derived from the local mountains (Figure 2.6); the Camp Rice Formation sediments are the Río Grande gravels and alluvium derived from upstream sources (Chapin and Seager, 1975; Collins and Raney, 1991) (Figure 2.7). The Fort Hancock is evenly bedded with fine texture and in Hudspeth County, based on borehole evidence (Strain, 1969), is 1067 m deep (Strain, 1980).

Mack and Seager (1990) place the appearance of the Río Grande in the Mesilla Basin at five Ma. In the Hueco Basin, Albritton and Smith (1968) and Gustavson

Figure 2.6A. Outcrop above Idalia Street showing playa sediments (east side, El Paso). Ordovician bedrock to right of photo.

Figure 2.6B Closer view of playa sediments at west end of Idalia Street (rod 2 m). Sand flats, mud flats, and debris flow deposits result of earthquakes or storms.

Figure 2.7. Camp Rice Formation as exposed in a road cut north of New Mexico Highway 404. Note cross-bedding (solid arrows) and soil contact (dashed arrow).

(1991), date the appearance of the Río Grande at 2.1 Ma. Along the Franklin Mountains, a series of terraces are observed that date to this inception of the Río Grande with river channel sands along the western side sand playa muds along the eastern flank atop the terraces. This constrains the highest terrace ages to between five and two Ma. These ages were determined by K/Ar dating of volcanic deposits (Chapin and Seager, 1975; Seager and others, 1984), vertebrate fauna (Strain, 1966; Metcalf, 1969) as well as studies of soil development on upper beds of the Camp Rice Formation, (Seager, 1980; Gile and others, 1981). The volcanic ashes found in the Camp Rice Formation match air-fall ashes from the Lava Creek Ash B dated at 640,000 years ago and two Ma. and Bishop ash from about 700,000 years ago (Gile and others, 1981).

Up to 150 m of Camp Rice Formation conglomerate and sandstone deposits in alluvial fans and alluvial flats are exposed in outcrops. The ancestral Río Grande left cross-beds and horizontally laminated pebbly sand/sandstone and mudstones that formed the terraces (Mack and others, 1998) (Figure 2.7).

The basins in the southern Río Grande rift were filled by rapidly aggrading fluvial and playa sediments which created broad, low gradient basin floors. For example, the La Mesa surface remains on the west side of the Río Grande (Gile and others, 1981). The aggradation during Fort Hancock and Camp Rice deposition buried the toes of the alluvial fans along the eastern flank of the Franklin Mountains, with the possible exception of the area near mouths of the two large canyons - Fusselman Canyon and McKelligon Canyon. Along most of the east flank of the mountain front, playa muds inter-tonguing with debris flows and thin alluvial fan gravels are exposed within a few

meters of bedrock (Figure 2.6A). Along the western flank of the mountain, fluvial sediments of the Camp Rice formation are intermittently exposed within a few tens of meters of the mountain front.

Intrenchment of the ancestral Río Grande system ended deposition of the Camp Rice Formation. The La Mesa Surface (middle Pleistocene) between the Río Grande valley floor and the East Portrillo and Robledo fault zones is 100 m above the current floodplain (Figure 2.8). It is approximately 780,000 year old (Mack and others, 1998). The surface is underlain by Camp Rice fluvial facies partially covered by Holocene sediments and coppice dunes. The surface sediments are gravelly strata that are resistant to erosion.

Unlike most ranges in extensional terraces, the Franklin Mountains are flanked by terraces composed of Fort Hancock and Camp Rice Formation sediments capped by thick alluvial fan gravels instead of growing together and becoming sloping bajadas. These terraces lie on the footwall of the east and west Franklin faults and were uplifted along with the footwall (Figure 2.9). Thus, these terraces record overall deformation of the range after their deposition.

Harbour (1972) first noted that terraces had been uplifted along the eastern flank of the Franklin Mountains. The only previous studies of the Franklin Terraces were those of Kottowski (1958) and Lovejoy (1975). Lovejoy (1975) documented 105 - 120 meters of basin-downward displacement of the terraces on the west side of the Franklin Mountains and suggested that the Franklin Mountains had been tilted two degrees to the west after deposition of the alluvial terraces due to relatively greater uplift on the East Franklin Fault (Figure 2.10). This configuration exhibits a classic half-graben tilt.

Figure 2.8. A - Schematic cross-sections of the Hueco Basin to the Río Grande Valley showing the progression that uplifted the terraces. A - the surface is eroded to previously lithified layers prior to Camp Rice deposition. B - deposition from floods caused by warming periods probably within the Nebraskan Glacial period or early Aftonian Interglacial period on the west side of the mountain; Fort Hancock sediments were deposited on east side of the mountain. C - later flow erodes the Camp Rice deposits shown in section B; the Fort Hancock sediments are faulted and begin developing alluvial fans along the East Franklin Fault Zone. D - after more faulting, uplift, and additional deposition, additional deposits form the lower terraces on the west side; the eastern side sediments continue to erode with the lower area being covered by bajadas along the mountain front.

Figure 1.9. East side of the Franklin Mountains, with Fort Hancock sediments in contact with the Precambrian mountain front. The contact is not immediately obvious when underfoot because of Precambrian rhyolite pieces that rolled over the alluvium. In picture A, the difference is the slope and the general roughness of the terrain above the arrow. (Photo above El Maida Shrine Temple in El Paso) The graph shows the slope that was measured using the GPS.

Figure 9B shows the same contact as seen along Scenic Drive a few meters north of the El Paso Police Academy.

Figure 2.10. Cartoon cross-section Z-Z' with 2 x vertical exaggeration showing dip from east side of Franklin mountains to west side. Section also shows approximate 150 meter difference between west terrace and elevation of La Mesa Surface west of Río Grande.

The terraces are the remains of a relatively smooth surface that now is disrupted by arroyos formed by down-cutting to the base-level of the Río Grande.

The entrenchment of the ancestral Río Grande system ended deposition of the Camp Rice Formation (Figure 2.11). During deposition of the Camp Rice and Fort Hancock Formations, uplift of the mountain blocks began to lift parts of this low-relief surface above the aggrading basin floors, causing deposition to stop and defining the uplifted terrace surfaces that are the subject of this study. "Uplifted terrace" is an appropriate term for the terraces that are the focus of this study; it is the term also used by Harbour (1972). The uplifted terraces are the remains of the original fluvial and lacustrine surface that formed the valley floor. The younger terraces, closer to the river were formed in a more traditional fashion - parallel to the river as it flowed through its valley.

As the terraces were uplifted, aggradation continued on the footwall block by Camp Rice and Fort Hancock sediments burying the equivalent surfaces in the subsiding Hueco and Mesilla Basins, until the 700,000 years ago incision of the Río Grande Valley commenced.

ROBLEDO MOUNTAIN

The Robledo Mountain exposes Paleozoic and Eocene age rocks that are tilted 10° to 14° to the south (Figure 2.1). Down-faulted blocks on both sides of the mountain are topped with fluvial Río Grande deposits. The Camp Rice Formation on-laps the southern part of the mountain (Hawley and others, 1975; Kottlowksi and Seager, 1998) as it does with the terraces observed in the Franklin Mountains. The East Robledo

Figure 2.11. West flank of the fault zone forms a dark, eroded band separating relict alluvial fans shown with upward pointing arrows along the mountain front. The gently sloping terrace surfaces are indicated by downward pointing, dashed arrows.

Fault cuts Camp Rice conglomerates exposing a sequence up to about 90 meters thick. Metcalf (1967) and Hawley and Kottowski (1969) saw three episodes of valley entrenchment followed by partial backfilling of the arroyos (Figure 2.12).

The East Robledo Fault has been active since late Pliocene as is shown by the comparative thicknesses of the Camp Rice sediments on either side of the fault. The sediments on the hanging wall side of the fault are appreciably deeper than the sediments on the footwall side of the fault (Mack and Seager, 1990) indicating the movement provided more fill space than had previously been available.

METHODS

A TRIMBLE Geo Xh, 2005 Series Pocket PC was used to acquire approximately 50 GPS-located elevations from both flanks of the Franklin Mountains as well as the La Mesa Surface from the Texas/New Mexico border to nearer the international boundary. The elevation of data were generally better than 30 cm and commonly better than 15 cm. The profiles of some uplifted terraces were measured along the crest of the terrace from the alluvial fan at the head of the slope break at the toe of the terrace; a reading was taken about every 70 cm. Measurements were estimated from the USGS 7½ minute topographic maps or DEMs in areas where the terraces were inaccessible as on the firing range at Fort Bliss.

Data from the La Mesa Surface along the western side of the Río Grande Valley in New Mexico were used as a control because there is evidence for much less deformation of this younger deposition surface. South of 32° N latitude, deformation of

Figure 2.12. Sierra Robledo, lines bound the area of greatest interest. This 500,000-600,000 year old surface maintains a slope parallel to the modern stream system.

Data were exported in UTM, zone 13N projection, and plotted in a variety of orientations to allow description of the geometries of the uplifted terrace. The measurements were taken where the slope was the flattest to minimize the younger alluvial fan deposits that fell and rolled onto the terrace proper.

RESULTS

Examination of uplifted terraces along the northern end of the range provided naturally exposed outcrops (Figure 2.13). Along most of the uplifted terraces, alluvial fans continued to build over the Camp Rice Formation. In the lower part of the terrace, however, the surface of the uplifted basin floor was better preserved near the toe of the terrace. After this discovery, the data were reexamined. Slopes were checked, the points used for comparison were moved from the head of the uplifted terraces to a point near the toe of the terraces where alluvium carried from the mountains has not obviously added to the elevation. Some of the terraces previously selected were probably alluvial fans instead of uplifted terraces. The younger alluvial fan deposits can be observed in aerial view but are nearly impossible to discern from ground level (Figure 2.9).

The alluvial fans have a steeper slope than the terraces. An oblique aerial view often gives some indication of the extent to which alluvial fans prograde over the terraces (Figure 2.14). At the toe of the terrace, the surface cover can be thin desert soil with a scattering of medium to coarse gravel or a well cemented cobble to boulder of varying thickness. The varying thickness of gravel creates noise in the interpreted terrace elevations, however, the magnitude of deformation due to uplift greatly exceeds

Figure 2.13A. Camp Rice sediments at Fillmore Gap as approached from the south.
Figure 2.13B Fillmore Gap from southwest - note extent of sediments

the noise resulting from fan deposition.

The uplifted terraces have been protected from erosion by a mantle of alluvial fan gravels of varying thicknesses. The structure of the terraces is revealed in exposures in the Robledo Mountains where recent erosion has dissected several terraces. The basin floor sediments, in this case fluvial sandbars, made the Camp Rice Formation, are tilted down and toward the mountain front to the west. This is inferred to result from down to the west rotation of the rising Robledo Fault Block. Alluvial fan gravels formed beds inclined to the east opposite to the basin fill and reveal a gradual progradation of an alluvial fan that grew across the rising terraces.

The terrace elevations, when plotted along the strike of the mountains, show a broad - 40 km long - asymmetrical anticlinal arch. The circles on the graph represent data points on the east side of the Franklin Mountains (Figure 2.15A and Figure 2.15B). The northern eight km of the eastern side rise 30 meters along a relatively gentle trend. From approximately 18 to 24 km, the slope Anthony's Nose (Figure 2.3), the slope changes again; it flattens to a 20 meter rise over nine kilometers. The high spot is 1364 m on the east side. East of that point, approximately 8.5 km north to approximately two kilometers from the southern end of the mountains, the slope of the terrace decreased to 39 m over 10.5 kilometers.

TERRACE MORPHOLOGY and STRATIGRAPHY

A typical uplifted terrace appears to be a relatively low gradient finger of higher topography extending from the mountains. The measured terraces are 85 to 150 m across and extend 140-350 m from the steeper alluvial fan portions. Crests of terraces

Figure 2.14A. Aerial view of the terraces west of the North Franklin Mountains. The difficulty in identifying fans vs terraces is that alluvial material is found nearly to toe of the terrace – without an arroyo or road cut, it is difficult to determine what is fan or what is terrace.

Figure 2.14B. Photo taken from New Mexico Highway 404 looking toward same area as A. Arrows pointing up highlight the terrace toes; the down arrows indicate more deeply dipping alluvial fans that bury the upper parts of the terraces against the mountain front. There is relatively little uplift along the western front of the North Franklins as compared to the central and southern parts of the range.

Figure 2.15. Graph A shows the La Mesa Surface - the flat line - as a control, with the west side terraces of the Franklin Mountains (square data points) and the east side points (designated with triangles). This plot is from Quantum GIS; the trend is hand-fit. The northern end of the North Franklin Mountains is buried under Camp Rice sediments so the northern end of the mountains is projected by the dashed line.

Figure 2.15B shows the same data and was plotted in Excel with the left Y axis for the same data as above as compared with the mountain peaks and passes (X points) plotted against the Y-axis on the right. The La Mesa Surface line is linear. The other three trend lines are third order polynomials.

are low gradient, with slopes of 5% to 10% from the mountain front. The flanks of the terraces are steeper, with slopes of 35% to 50%. Figure 16 illustrates the form of the terraces. Many of the larger terraces are associated with canyon mouths and arroyos that exit the canyons and are diverted along the mountain front for a short distance before continuing between the terrace remnants. This suggests that early alluvial gravel deposition in the upper terraces protected the terraces from erosion; the more exposed areas flanking the canyons have less gravel so were more vulnerable to incision.

Along their bases and flanks, the terraces merge with steeper slopes that form their margins. On the mountain side of the terraces, they commonly merge into steeper intervals (Figure 2.6A). The surfaces of these steeper intervals are littered with coarse, angular clasts from the adjacent mountain slopes; these are interpreted as relict alluvial fans, now isolated by incision of the drainages. The boundary between the alluvial fan and terrace can be difficult to identify in the field as it is marked by a gradual increase in slope angle (Figure 2.9).

The internal structure of the uplifted terraces is difficult to observe as the strata are usually covered by indurated Pleistocene or Holocene calcic soils that, except where exposed by arroyo incision, obscure the stratigraphy and structure of the terraces. Several uplifted terraces in the Robledo Mountains are incised through their length and expose both the internal structure and stratigraphy (Figure 2.7). The strata consist of fine- to medium-grained sands of the Camp Rice Formation that are dipping into the Robledo Mountains block at 2-4 degrees. This tilting is similar, but at lower angles than the overall tilt of the range. This is ascribed to tilting of the hanging wall

Figure 2.16. Comparison of the terrace above the water tank with the next terrace north – southern group of terraces on west side, Figure 2.2

block during extensional deformation. Similar strata are exposed along both flanks of the Franklin Mountains, but the limited exposures preclude estimates of the dip of the bedding.

In the well-exposed Robledo examples, the basin floor strata are overlain by crude layers of coarse gravel that dip basinward. These beds lap onto the basin floor sediments and are truncated at the top (Figure 2.12). They are inferred to represent the progradation of fan gravels across the sediments prior to erosion during the uplift of the hanging wall on which they sit. The terrace surface overlying these inclined strata is much flatter and appears to be an almost horizontal finger extending from the range front, similar to those in the Franklin Mountains.

The important lesson of the Robledo examples is that there are relatively thick gravels extending across the terrace and the surface that is measured today is an erosional surface that is higher by as much as 15 m than the uplifted basin floor. The data from the Franklin Mountains, described below, contains considerable noise in the form of varying elevations in adjacent terraces. This is attributed to varying thicknesses of gravels, ranging to 25 m, that bury the basin floor sediments. Early in this research, the heads of the terraces were measured as these were thought to exhibit less potential erosion, but greater noise was found within the data. Terraces were then re-measured near their toes where the gravel cover thickness was minimized. Observed thicknesses of gravels capping the uplifted terraces vary from no cover in the northern Franklin Mountains to over 15 m in the central and southern Franklin Mountains. The thickest observed gravel was in one dissected terrace in Robledo Mountain that exposed 30 m of gravel near the mountain fronts. Unexposed gravel thicknesses may reach 25 m as

this is the mean maximum variation between adjacent terrace surfaces in the Franklin Mountains (Figure 2.15).

The uplifted terraces have been deformed from an initially planar surface that filled the entire area to the west side of the incipient mountains into a broad anticlinal arch that is highest near North Franklin Peak in the central part of the range (Figure 3). The uplifted terraces on the east side of the Franklin Mountains appear to be approximately 20 m higher than the uplifted terraces on the west side of the Franklin Mountains but the eastern high points are three kilometers south of the high points on the western side of the mountain. The east side of the mountains also does not exhibit the multiple terraces that are found on the west side. The highest terraces on the east side are at 1370 m elevation, approximately 120 m above the La Mesa Surface (Figure 2.15). This represents a minimum uplift as the floors of the Hueco and Mesilla Basins are younger and the equivalent surface to that of the terraces is buried under an unknown thickness of younger sediment.

At the north end of the range, the topography is flat although still 22 m higher than the La Mesa Surface. This surface is underlain by fluvial channel sands of the Camp Rice Formation (Hawley and Kottowski, 1969). Lava Creek B Ash in the uppermost fill of Fillmore Gap dates the uplift of the Fillmore Gap surface to post two Ma (Bachman and Mehnert, 1978). The Fillmore Gap segment, also, is not deformed as are the terraces to the south. This leads to the inference that the Fillmore Gap is a younger terrace that formed on sediment that buried the older terrace where uplift was less than uplift in the rest of the Franklin Mountains.

The La Mesa surface forms a low gradient surface with an elevation of 1253.6 m

elevation at the Santa Teresa Airport (Figure 2.15A, Figure 2.15B). The uplifted terraces on both the east and west sides of the Franklin Mountains are higher than the La Mesa surface on the west side of the present Río Grande Valley. The La Mesa Surface has not been deformed and so preserves the southerly gradient of the paleo-Río Grande. A surveyed point at the Las Cruces, New Mexico air port is 1354 meters. This is 101 m higher than the Santa Teresa Airport 50.5 km to the south.

There may be two sets of uplifted terraces on the west side. The gray line and inverted triangles show data found on the west side of the Franklin Mountains. The bold line also traces a broad, asymmetric anticline (Figure 2.15A, 2. Figure 15B). Erosion no doubt has reduced the peaks. The third order polynomial trend lines for the mountain peaks and the elevations of the terraces have similar shape. The La Mesa Surface across the bottom of the graph is best described as linear.

DISCUSSION

Previous models of deformation associated with extension tectonics have largely been oriented perpendicular to the structures. The data presented here constrains these models as it presents along-fault-strike data. The older terraces have been deformed by mountain uplift into a broad anticline that extends the length of the range. Figure 15B, right axis, shows the curve that mimics the elevations along the mountain crest. Because of this extensive deformation, the surface probably dates more closely to five million years. The uplifted terraces flanking the Franklin Mountains can be dated to between five million years when the Río Grande appeared in the Mesilla Basin, and two million years when the river flowed through Fillmore Gap at the north end of the

range (Figure 2.2, Figure 2.13). The uplifted, but generally horizontal surface flanking the northern part of the range probably dates to near the two million year date and buries the older, deformed terraces.

In contrast, the La Mesa Surface has essentially been undeformed and only weakly incised since it was deposited approximately 700,000 years ago. The only way the terraces could have risen above the La Mesa surface from their original elevations is for them to have risen along with the mountains. The terraces at the crest of the anticlines have been uplifted 110 m above the undeformed and only weakly incised La Mesa Surface. Because the La Mesa Surface is much younger than the Franklin Mountains and basin floor aggradation continued during the deformation of the range, the 100 m uplift represents a minimum uplift of the terraces.

The uplifted terrace elevations correlate with the range crest elevations, deformation by the faults may correlate with range topography thus implying a low relief surface prior to deformation on the East Franklin Fault.

This prompts the question, "What shaped the uplift of the range?" Of the various mechanisms for uplift associated with extensional deformation, only the flexural model of Brown and Phillips (1999), or the block rotation model of Melosh and Williams's (1989) and Melosh's (1990) numerical analysis model provides uplift that is associated with the magnitude of faulting observed and are supported by the data in the Franklin Mountains. These models also imply that uplift of the mountains should largely correlate with deformation along the East Franklin Fault. As the East Franklin Boundary Fault rotated the eastern side upwards, it also lifted the west side of the mountains.

Gravity maps (Marrufo, 2011) show that the gravity low indicating the deepest

part of the Hueco Basin is opposite the central and southern parts of the Franklin Mountains. This is the area where terrace uplift is greatest. Opposite the northern end of the range, the fault veers to the northeast end and becomes less of a half-graben and more of a graben, correlating with the lower topography of the range front.

The terraces along the east side of the mountain are as much as 20 m higher than the terraces on the west side (Figure 2.10, Figure 2.15A, Figure 2.15B). If the terraces were originally at nearly the same elevation; the 20 m difference across the 4000 m width of the mountain represents a 2-degree rotation of the Franklin Mountain block after terrace deformation. Lovejoy (1971) also described this difference as resulting from a 2.3-degree rotation of the Franklin Mountain block.

As described above, the Franklin Mountains form a complex tilted horst with the major boundary fault on the east flank and a broad complex of faults separating it from the Mesilla Basin to the west. The West Franklin fault zone was inactive after deposition of the uplifted terraces and does not offset the terraces (Scharman, 2006). However, faults near the modern course of the Río Grande offset the Camp Rice fluvial deposits and terraces flanking the river. Using a horizontal plane extending from the west mesa and a two degree inclination from the uplifted terraces provides a pivot-point west of the mountain front. Assuming 150 m of deposition, burying the surface in the Mesilla Basin equivalent to the terrace depositional surface results in a 300 m elevation difference and a pivot point approximately 8.6 km west of the mountains near the trace of the Mesilla Valley Fault.

The deformation of the older uplifted terraces presents an unusual opportunity to measure the long-term uplift of the extensional Franklin Mountain block. The rapid

aggradation during the Pliocene buried the mountain front and created nearly horizontal surfaces that have been deformed by long-term deformation.

Three key observations can be derived from this deformation. First, the deformation mimics range topography. This has important implications for understanding the pre-extensional topography of the region. The correlation between deformation and topography implies that excepting volcanic edifices, topography in the region has a low relief surface. This leads to the inference that topography in the southern Río Grande rift is largely tectonic and not inherited. Several authors have discussed the potential for inherited topography in the northern Río Grande rift (Chapin and Cather, 1994; May and others, 1994; Lucas and others, 1999) however this does not seem to be a factor in the El Paso area.

The second observation is where there is true uplift of the Franklin Mountains resulting from either flexure or from mid-crustal flow, in both cases, the uplift is related to extension on the East Franklin Fault.

The third observation is that the terraces show differential uplift that correlates with displacement on the East Franklin Fault. Two models can account for this observation.

Model one contains no uplift of the range, but rather exhumation of the range results from the greater subsidence of the Hueco and Mesilla Basin blocks. Model two relies on flexure and uses gravity and mid-crustal flow to explain the movements.

There are two models of uplift that appear to fit the observed motions of the Franklin Mountains. The first model for uplift of the mountains flanking the Río Grande rift is that of Roy and others (1999), who used a flexural model to show how mountains

can develop in an extensional setting. They show that ranges developed along rift settings with the steep side facing the fault zone have a gentle up-warp on the other side. Some of this up-warp may be related to isostatic unloading adjacent to the fault. Flexural uplift appears to be most apparent in areas with a single master fault and asymmetric basins (Roy and others, 1999).

Perhaps the best model to explain uplift of the Franklin Mountains is proposed by Brown and Phillips (1999). They agree that uplifts may be due to more than one mechanism. They considered that the flanks of the section of the rift including the Sacramento Mountains to extend east approximately 150 km to the Pecos River valley. The Sacramento Mountains are the only one of several mountain chains bounding the Río Grande Rift that Brown and Phillips (1999) feel fits the flexural rift flank model. The Sacramento Mountains are not complicated by earlier tectonism along the eastern side of the range, therefore, they are simple to model as a flexure.

Brown and Phillips (1999) examined several possible flexural models including Zandt and Owens's (1980) elastic plate model and broken plate models. Thermal and mechanical processes were proposed to explain the rift flank relief. They concluded that both broad thermal uplift and narrower flexure combine to create the uplift of the Sacramento Mountains.

A second model that makes sense in this area is that of Melosh and Williams (1989) and Melosh (1990) (Figure 2.17). They used a finite element model to create a flexural model in which the flow in the ductile middle crust allows deformation of the thick upper crust. They include only gravity as a vertical stress though they state that extension could result from regional doming or flexure on a broader scale than crustal

Figure 2.17A . Results from the finite element run. Note the diagonal at the base of finite element model as well as the top of the figure.

Figure 2.17B. Figure shows an enlargement of the area beneath the fault in the model run.

thicknesses or proximity to tectonic features. When the elastic upper layer is displaced horizontally with respect to a lower elastic layer, the sandwiched viscous layer is subject to simple shear (Melosh, 1990). The principle stress orientation is oriented 45 degrees to vertical. Melosh (1990) relies on the rheological structure of the crust combined with high heat flow and stresses within the crust to run the finite element analysis mode. This resulted in uplift of the footwall block through rotation of the normal fault with resulting spatial gap filled through viscous flow (Melosh, 1990)

Other models do not appear to work in the southern Río Grande area. May and others (1994) believe the flank uplift results from isostatic rebound due to tectonic unloading of the lithosphere rather than from flexure. Manning and Bartley (1994); Axen and others (1995); and Wernicke and Axen (1998) believe flexural faulting aided by isostatic forces produce rotational folding in the eastern Basin and Range. Isostatic rebound prompted by unloading is the preferred mechanism behind faulting as studied by Buck (1988); Weissel and Karner (1989); and Wernicke and Axen (1998).

CONCLUSIONS

Because the geometry of the uplifted terraces match the mountain crests, a tectonic origin is implied. This also implies a low relief surface prior to deformation.

Uplift on the eastern flank resulted in a two degree rotation of the uplifted terraces. This combined with terrace geometry implies differential slip on the East Franklin Fault Zone controls terrace deformation and resulted in asymmetric anticline into which the terraces deformed. The rotation down to the west implies a rotational point west of the range.

Anticlinal uplift of the terraces may be due to either differential subsidence or tectonic uplift of the Franklin Mountain block. Tectonic uplift can be explained by either Melosh, 1990), Melosh and Williams, 1989), or Brown and Phillips (1999).

CHAPTER 3: INFLUENCE OF EXTENSIONAL UPLIFT AND TOPOGRAPHY IN THE SOUTHERN BASIN AND RANGE / RÍO GRANDE RIFT, THE INFLUENCE OF TECTONISM ON TOPOGRAPHY

ABSTRACT

In an earlier study, long-term tectonic deformation of the Franklin Mountains was documented indicating over a hundred meters of uplift in the Late Pliocene and Pleistocene. One observation in the Franklin Mountains study was that the overall range topography mimicked the tectonic uplift that was documented in Pliocene terraces. A hypothesis from this study was that the topography of the was tectonic in origin, and the topography of the range reflected deformation of an originally low-relief surface that existed prior to Río Grande Rift deformation.

This study is a comparison to the other topographically high mountains in the area; the Guadalupe, San Andres, and Sacramento Mountains are well-studied examples that should allow for inferences about whether the observed topography is also tectonic in origin. The study applies information from other researchers about the history of deformation in the Guadalupe, the San Andres, and Sacramento Mountains. Uranium-Lead dates from other researchers of caves in the Guadalupe Mountains show that the range was near the water table 11.4 Ma; the water table was preserved in the caves and shows an uplift of at least 855 m. The Sacramento Mountains show that the low-relief mountain crest has been near the surface since the Mesozoic with little denudation of the surface and no evident pre-Rift deformation of the area.

Along with other researcher's results that show little pre-rift, deformation, the

the long-wavelength topography of the southern Rift. A surface that eliminates structural basins and erosional valleys shows that the Guadalupe Mountains and Sacramento Mountains extend well above this smooth surface, as do the other ranges in the area that have significant Holocene faulting along their escarpments.

The four range peaks stand significantly above the surface. Guadalupe Mountains stand about 325 m above the polynomial surface that describes the uneroded surface of a long wave-length surface. The Franklin Mountains are 350 m above the surface, the Sacramento Mountains rise approximately 1 km above the model surface, and the southern San Andres Mountains Salinas Peak protrudes approximately 600 m above the surface.

INTRODUCTION

This study compares uplift histories and geometries of four ranges along the eastern side of the Basin and Range Province (Figure 3.1). The ranges are within the southern extension of the Río Grande Rift where it merges into the Basin and Range Province (Chapin, 1971, 1979; Seager and Morgan, 1979). The Franklin and San Andres Mountains are part of the Mexican Highlands section of the Basin and Range; the Sacramento Section of the Basin and Range that Fenneman (1928, 1931) defined as “a belt on its [Basin and Range] eastern margin, whose mountains are in large part simple dissected *cuestas*”, includes the Sacramento and Guadalupe Mountains. The Sacramento Section is physiographically defined as “the broad upland between the Río Grande and half-way to the Pecos Valley” (Fenneman, 1928).

Does range topography in this part of the Basin and Range/Río Grande Rift

Figure 3.1 Generalized index map of Trans-Pecos Texas and south central New Mexico. The main faults associated with the Guadalupe, Sacramento, and Hueco Mountains are on the western side of the ranges. The primary bounding faults for the San Andres and Franklin Mountains are on the eastern side of the ranges. (after Hayes, 1964)

represent deformation of an older, low relief surface? Can Basin and Range long-term tectonism be used to estimate range topography? In a previous chapter, the long-term uplift of the Franklin Mountains, in the southern Río Grande Rift was inferred from uplifted Pliocene terraces. This paper will investigate these questions by comparing the mountain ranges with the results of the study of the Franklin Mountains with the nearest high relief mountains; the San Andres, Sacramento and Guadalupe Mountains.

One important result of an earlier Franklin Mountain study (Armour, 2014) was that the range topography mimicked the uplift and that the topography was largely tectonic. Terraces along the sides of the Franklin Mountains mimic the arch formed along the crest of the mountains (Figure 3.2). The long-term deformation of these terraces implied that the topography of the range is largely tectonic in origin and that prior to Late Tertiary extensional deformation, the area was a low relief plain.

Uplifting of the terraces suggests that the topography may also be an indication of uplift of other ranges in the area. More importantly, it suggests that, at least for this part of the Basin and Range, topography can be used as a crude proxy for extensional tectonism in the region. The largest uplifts in the area are those of the San Andres, Sacramento and Guadalupe uplifts. This chapter will compare range topography with evidence for the amplitude of deformation.

All of these ranges are bounded on one side by a master fault (Figure 3.1). A half graben down to the west forms the relatively gently sloping side of the Hueco Basin east of the Franklin Mountains. The Hueco Mountains east of the Hueco Basin merge by way of Otero Mesa with the Sacramento Mountains to the north. The Sacramento Mountains present a steep face to the west but the difference between Cathy Peak and

Figure 3.2 Graph showing terraces from east and west flanks of the Franklin Mountains with the trace of the mountain crest shown by Xs. The fact that the uplifts follow similar curves indicates that the mountains and terraces were uplifted together.

the Pecos River is approximately 1950 m over 170 km for an average slope of 1.15%. The main fault for the Guadalupe Mountains is on the west side of the range with the majority of the east side of the range sloping gently to the Pecos River. A myriad of small faults plus erosion has exposed the reef face on the east side to at least Walnut Canyon approximately 55 km north of the southern expression of the Guadalupe Mountains. The San Andres Mountains have their primary fault again on the east side adjacent to the Tularosa Basin; this range slopes into the Jornada del Muerto (Figure 3.1).

SACRAMENTO MOUNTAINS

The Sacramento Mountains extend from approximately 34° N to 32.5° N where they merge with the Otero Mesa. In north-south profile, the crest of the Sacramento Mountains forms a gentle arch (Pray, 1961). Yeso and Abo Formations (Permian Leonardian, 275-270 Ma) are found at Cathey Peak, the highest peak (2955 m) of the Sacramento Mountains of southern New Mexico. Cathey Peak is 1633 m above Alamogordo, New Mexico, the town for which the bounding western fault is named. Like the Franklin Mountains, the escarpment of the Sacramento Mountains is relatively abrupt with low pediments along the faulted west side and few fans at the mouths of canyons. There are a few treads and benches at formation contacts along the faulted face of the Sacramento Mountains but there are no terraces as with the Franklin Mountains. Pray's (1961) Figure 4 shows this well.

The Sacramento Mountains are part of an uplift that extends 109 km along the Alamogordo Fault and bounds the western side of the Sacramento Mountains

separating the mountains from the Tularosa Basin (Machette and Kelson, 1996). The fault extends south nearly to the Hueco Mountains where it terminates among a series of “anastomosing” (Collins and Raney, 1997) faults that continue the trend south into Trans-Pecos Texas. A pair of un-named faults that continue the trend bound the west side of the low Hueco Mountains (Collins and Raney, 1991). Farther south, relatively small faults break the surface of the Hueco Basin (Collins and Raney, 2000).

The Alamogordo Fault appears from description to be a fault zone (Pray, 1961) as are the East Franklin Fault of the Franklin Mountains and the Border Fault of the Guadalupe Mountains. The Alamogordo Fault dip is at high angle to the west with dip-slip movement; scarps to about 25 m displace alluvium and other piedmont surfaces exposing bedrock on the footwall side.

Ramberg and others (1978) attempted to model the gravity of the southern Río Grande Basin as it integrates with the Basin and Range Physiographic province. Ramberg and others (1978) had to manipulate their data in order to remove known geological features including Laramide structures, Ancestral Rockies features, and Tertiary intrusives to obtain observed elevations and known depths as shown in their Figures 3, 4, and 6 on pages 110 -112.

The high along the crest of the Sacramento Mountains is reported at approximately 32°45.5' N, 105°48' W; the city of Alamogordo is reported near, 32° 51' N, 105° 58' W (Wikipedia). The isopach maps (Raatz and others, 2002) indicate the thickest portion of the basin is west and north of Alamogordo. Based on this information, the low of the eastern side of the Tularosa Basin appears to be in the proximity of the high points of the mountains similar to Marrufo's (2011) findings

associated with the Hueco Basin and Franklin Mountains.

GUADALUPE MOUNTAINS

Beginning 64 km to the south and east of the Sacramento Mountains, the Border Fault bounds the west side of the Guadalupe, Delaware, and Apache Mountains. The Guadalupe Mountains at the northern end of the group are the highest of the trio of mountains. Guadalupe Peak is the highest elevation in Texas at 2667 m; it is topped by Permian Guadalupian age (270 - 260 Ma) formations. The uplift extends from the Sacramento Mountains south along the eastern edge of the Salt Basin to the Oligocene age Davis Mountains, a total of 240 km. The Guadalupe, Delaware, and Apache Mountains are a late-Tertiary Basin and Range feature that extends from approximately 50 km north of the 32nd parallel to 25 km south of the parallel.

The Guadalupe Mountains form a wedge-shaped feature with the southern end at El Capitan being a prominent escarpment. A few kilometers to the north is Guadalupe Peak. The western or main portion of the Guadalupe Mountains extends northwest from El Capitan and Guadalupe Peak toward the Sacramento Mountains approximately 110 km (Hill, 1996). The Northeastern Prong forms the eastern side of the wedge.

Except for the erosional topography along the southwest - northeast trend of the Permian Reef, the Guadalupe Mountain's topography dips gently toward the Pecos River and the sub-surface Delaware Basin to the east. The Guadalupe Ridge was part of a reef that surrounded the Permian age Delaware Basin. Uplift of this section of the reef suggests compaction and subsidence rather than compression. King (1948) noted

that a widespread erosional surface intersected the Guadalupe Ridge folds and other prominences, indicating that the folds probably were pre-Laramide.

Movement along the Border Fault zone between the Guadalupe Mountain and Salt Graben has been right-lateral trans-tensional (Goetz, 1985). The area between the Border Fault and the Hueco Mountains to the west of the Guadalupe Mountains is considered by some to be a younger extension of the Río Grande Rift (Keller and Peeples, 1985; Goetz, 1985). Others consider the average 500 m of Cenozoic fill in the northern Salt Graben near the Guadalupe Mountains to be insufficient for it to be considered part of the Rift (Seager and Morgan, 1979). Three wells were drilled in the mid-Salt Graben near the central section of the Delaware Mountains. Their depths exceeded 747 m (Trentham, personal communication, 2013) so portions of the Graben are deeper than the depth of the most studied portion of the area.

Three additional features between the City of Carlsbad and El Capitan are covered by geomorphic surfaces that some refer to as terraces (Hill, 1998). Like the terraces that flank the Franklin Mountains, these surfaces are believed to be constructional and can be correlated with the glacial and interglacial stages. They formed within the last 600,000 years and have slopes of 0.9%, similar to the slope of the La Mesa Surface west of the Franklin Mountains (Aristarain, 1971; Hawley and others, 1976; Hawley, 1993b). The oldest surface, the Blackdom, was described by Meinzer and others (1926) as a "well-defined...older terrace". This one most nearly correlates with the Camp Rice Formation that forms the terraces around the Franklin Mountains.. The Orchard Park and Lakewood terraces are of similar age to the younger formations of the Mesilla Valley and the Franklin Mountain area (Hall, 1998).

Examination of three USGS 30° by 60° topographic maps gives some indication that the Guadalupe and Delaware Mountains may also have deformed and uplifted similar to the deformation of terraces that flank the Franklin Mountains. The 1000 m contour interval (CI) was compared to the Pecos River which the contour did not follow. The 1200 m and 1400 m contours were checked to determine whether they showed any relation to the 1600 m contour which is near the crest of the Apache and Delaware Mountains. The 1600 CI does not extend to the north end of Carlsbad National Park. The 1400 m CI needs further examination to discover whether it includes the Blackdom surface or if it crosses the Orchard Park or Lakewood terraces.

SAN ANDRES MOUNTAINS

The San Andres Mountains are difficult to study because the San Andres Fault along the east side of the range is on the White Sands Missile Range and access has been limited since the mid-1940s. The two highest peaks within the San Andres Mountains are at either end of the range. San Andres Peak (2510 m) is 770 m above the Tularosa Basin and is of greatest interest for this study as it is stratigraphic in nature. San Andres Peak is composed primarily of PreCambrian and Paleozoic rocks; Salinas Peak on the north end of the range is volcanic with an AFT age of approximately 50 Ma (Kelley, 1997).

The San Andres Fault that bounds the east side of the range can be divided into three segments. Machette's (1996) three studies completed for the USGS describes the southern fault segment as merging on the southern end with the Organ Fault extending into the northern end of the Tularosa Basin. Kelley (1997) was allowed

access to the east side of the range to gather samples with apatite and uranium. She found that the range began uplift and cooling about 21 to 22 Ma; she also found AFT ages of 7 to 8 Ma, or Middle Miocene indicating uplift of the San Andres Mountains is associated with the opening of the Río Grande Rift.

METHODS

Because uplift associated with extension should also correlate with deeper basin subsidence, elevation data along 32° and 33° north were extracted from transects shown in Figures 3.3 and 3.4 . The profile following 32° north (Figure 3.5) extends from the Pecos River where it crosses from New Mexico into Texas at -104° W and west past the Chiricahua Mountains in Arizona. This profile includes both the Guadalupe and Franklin Mountains associated with this study. The transect along 33° north (Figure 3.5) also begins at -104° W in the Great Plains of New Mexico, crosses the Sacramento, the southern end of the San Andres Mountains, and the southern transition zone between the Basin and Range and the Colorado Plateau extending into Arizona where the Santa Teresa Mountains protrude above the smoothed surface.

In order to evaluate whether the digital elevation model (DEM) showing the topography of the region illustrates the uplifts, the DEM data were combined with gravity data for an area bounded by parallels 31° and 35° N and Longitude -104 to -110° W. One third arc-second DEMs were obtained from the U.S. Geological Survey National Map, were merged and reprojected to UTM Zone 13. The area includes the Pecos Valley and high plains of eastern New Mexico on the east and extends beyond the Chiricahua Mountains to the west.

Figure 3.3 Topographic profile along 32° N including both Guadalupe Mountains, the most eastern peak, and Franklin Mountains, the third peak from the east.

Figure 3.4 Topographic profile across Latitude 33° N with second-order polynomial curve. Sacramento, southern San Andres, and Penaleño Mountains extend well above curve.

Figure 3.5 Map constructed on polynomial fit surface shown in Figures 3.3 and 3.4. Guadalupe Mountains on the right with Delaware Mountains extending to the bottom of the map; Sacramento Mountains are near top center. Franklin Mountains are too narrow to see at this scale though they stand 250 m above the surface.

Several smoothing equations were tested including least squares, several polynomial surfaces, cubic spline, and logarithmic fits. Of these, the polynomial surface provided the best fit to the data. Polynomial surfaces of order 2 in the X direction and 2 in the Y direction were compared to higher order polynomials up to 4th order in the X and 4th order in the Y directions. No significant differences among these surfaces were found, and the 2nd order by 2nd order polynomial surface provided the best fit with an R² value of 0.94. Therefore, the long wave-length topography in the southern Río Grande Rift is best modeled by a three-dimensional parabolic surface. The transects provide profiles similar to the observations by Roy and others (1999) and Brown and Phillips (1999) in their observations of the Alvarado Ridge and thermal buoyancy affects in this area.

TOPOGRAPHIC RESULTS

The results show several important features. The Río Grande Rift sits within a long wavelength topographic high that has been discussed by many authors (Eaton, 1987; Brown and Phillips, 1999; Roy and others, 1999). The Guadalupe, Sacramento, San Andres, and Franklin Mountains lie well above the long wavelength surface. Real uplift as hypothesized in the second paper of this dissertation is tectonic in origin (Figure 3.4, Figure 3.5). These results support the similar studies of uplift of the Sacramento Mountains. by Roy and others, (1999) and Brown and Phillips (1999).

These results contrast with those of Eaton, (1987), who described an Oligocene to Miocene uplift, the Alvarado Ridge, a Neogene uplift which is presumed to include the study area. He predicts heat induced buoyancy may be responsible for the regional

uplift of the mountains and high basins of the southern Río Grande Rift and surrounding area. A slightly later proposal involves the Alvarado Ridge uplift and fragmentation resulting from the development of the Río Grande. The Alvarado Ridge is also an extensional feature, similar in profile to the ocean ridges. The projections shown in Eaton's (1987) Figure 8c shows the Río Grande Rift as the center of the ridge. Pertinent to this study is the topographic profile across 33° N latitude that is similar to the profile of Brown and Phillips (1999).

A map was constructed (Figure 3.3) on the polynomial fit surfaces shown as cross-sections in Figures 3.4 and 3.5. The Franklin, San Andres, Sacramento and Guadalupe Mountains are uplifted by 200 m to 1 km above the regional surface. The Franklin Mountains are located by the arrow as they are difficult to see at this scale. The Franklin Mountains protrude approximately 250 m above the polynomial surface; the Guadalupe Mountains extend approximately 235 m; the Sacramento Mountains reach nearly one km, and the southern end of the San Andres Mountains extend about 600 m above the smoothed surface.

Most of the topography lies below the smoothed surface except in the northern part of the map where almost all of the terrain lies above the smoothed surface (Figure 3.3). This north-south lack of fit results from the origin of the smoothed surface modeled from east-west transects. Many smaller scale topographic features are also evident. In addition to the Guadalupe, Franklins, southern San Andres, and Sacramentos, the Chiricahuas and Pinalaños show up as block uplifts.

The Gila Volcanic Plateau forms a broad upland in the northwest corner of the map. The Black Range, San Mateo and Gallinas ranges, parts of the Plateau, for

Figure 3.6 Bouguer anomaly map normalized to topography from New Mexico/Arizona border on the west to the Pecos River on the east. (Montana, 2014)

topographic highs that extend southward off the Gila Plateau and the Manzano Mountains. They mark the eastern high that would be expected. They also represent broad topographic uplift to the north of edge of a well-defined rift valley along the north end of the smoothed map surface. All of these lie at least 200 meters above the smoothed surface. Some of the uplifts, especially the Gila are volcanic highlands composed of Oligocene tuffs. The other ranges appear to be flexural uplifts similar to the Franklins as discussed in Chapter 2. The uplifts are all elongate north-south, symmetrical anticlines gently plunging north and south similar to the Franklins and are 30 to 50 km long.

GRAVITY RESULTS

Figure 3.4 shows a map compiled from The University of Texas at El Paso's PACES database. Generic Mapping Tools (GMT) was used with high-resolution free-air anomaly to filter and model a combination gravity / topographic map of the area between 31° N, -104° W to 35° N, -109° W. The resulting map by Montana (2014) shows known topography. For Figure 3.6, the gravity was re-scaled from zero, the highest gravity value and one for lowest gravity value. The topography was scaled so the topographic high is one and low is zero. The scaled results were multiplied together to produce a gravity / topographic composite (Montana, personal communication, 2014). This map emphasizes locations where topographic lows and gravity lows coincide such as in structural basins.

On the gravity map, the Gila Volcanic Plateau forms a prominent low (Figure 3.2). This probably results from low density intrusives in the crust beneath the plateau.

This map does not extend westward far enough to image the prominent highs of the Chiracahuas and Pinalaños. However, most of the other uplifts visible above the smoothed topographic surface exhibit prominent gravity lows suggesting deep basin fills adjacent to these mountains. Blue shaded gravity lows can be seen adjacent to the Sacramentos, Guadalupe, Franklins, and San Andres Mountains (Figure 3.6).

Gravity lows also coincide with deep basins as resistivity and well logs. This compares to basins outside of the rift that are generally more shallow than 1000 m. (Seager and Morgan, 1979, their Figure 3). Goetz (1980) used resistivity and well records to determine a depth of approximately 900 m for the Salt Graben which agrees with Trentham (2013). The western part of the Tularosa half graben holds approximately 2000 m of Neogene sediments (Zohdy, 1969; Doty and Cooper, 1970). Lake sediments were detected to 1585 m of stratigraphic test well that reached 1833 m near the White Sands Missile Range Headquarters (McLean, 1975). The trough along the western side of the Hueco Basin is filled with about 2700 m of sediments according to Mattick (1967) and Gates and others, (1978).

TIMING OF BASIN AND RANGE DEFORMATION

Deformation recorded in the Franklin Mountains (Chapter 2) and evidence from the topography (Figure 3.2) and the gravity (Figure 3.6) data suggest that the southern Río Grande Rift represents deformation of a low relief surface. Data from the Guadalupe and Sacramento Mountains provide the timing of this deformation.

The uplift of the Guadalupe Mountains has been determined by dating caves in the mountains. Approximately 300 caves are found along the Guadalupe Mountains

(DuChene and others, 1999). A hydrologic connection between the Capitan Limestone and the Pecos River aquifer that had developed within the reef. Its level was controlled by the regional base-level of the Pecos River (Hill, 1987). Acidic water dissolves the carbonate formations as it follows the joints within the formations (Jagnow, 1977, 1979; Hinds and Cunningham, 1970). Of key importance is that acidification and cave dissolution occurred at the water table, and therefore, caves in the Guadalupe Mountains record paleo-water tables.

The highest cave along the Guadalupe Mountain trend is Virgin Cave (Figure 3.7). The surface elevation is 2001 m, the deepest accessible point of the cave is 1892 m. Carlsbad Cavern is the lowest of the known major caves of the Guadalupe Mountain escarpment. Carlsbad Cavern is dated at 4 Ma using uranium alunite method (Mosch and Polyak, 1996; Polyak and Güven, 1996). Uranium series dating of cave spar indicates an age of $879,000 \pm 124,000$ years but probably formed above the water table. Uplift began from a low relief surface about 12 Ma.

Similar results are obtained from the Sacramento Mountains. Apatite Fission-Track (AFT) analysis has been analyzed by Kelley and Chapin (1997) for several mountain ranges within southern New Mexico and far western Texas. AFT cooling ages for the Franklin, Sacramento, and San Andres Mountains were calculated from samples taken near the crests of the mountains. Samples from the crests of the Sacramento and Franklin Mountains exhibit fission track ages of 112 Ma and 51 partial annealing zone (PAZ) results for both of these ranges. This implies relatively shallow burial during the late Cretaceous and little erosion at the range crests. Kelley and Chapin (1997) suggest an episode of uplift at about 35 Ma and a much more

Figure 3.7 Elevation of five caves in Guadalupe Mountains plotted against U-Pb age in million years.

significant uplift and unroofing during the last 20 Ma. Ages that fall within the 7 to 8 Ma range indicate middle Miocene cooling associated with uplift during extension. Similar young ages are observed in the major flank uplifts of the Río Grande rift (Kelley and Chapin, 1997). House and others (2003) conducted a detailed examination of Sandia Mountains. They concluded that there were 3.1 km of uplift along with 2.4 km of flexural, fault-related uplift in the Sandias. Furthermore, similar to this paper, they inferred that the local topography was associated with flexure on the rift-flank fault. And finally, they concluded that almost all of this occurred within the last 15 Ma. It therefore appears that the inferences from the Franklins, Sacramentos, San Andres, and Guadalupe are broadly applicable across the region.

DISCUSSION

Coincident with the theory that topography reflects Basin and Range tectonics, is that these ranges all have long been thought to have been low features if not peneplained during the Laramide (King, 1948; Pray, 1961; Hall, 1987). The Franklin Mountains, as seen today, are the result of Precambrian uplifting and granitic intrusions; early Paleozoic quiescence culminated in Permian folding; Mesozoic compression and tension; and finally Neogene tension and faulting raising the previously deposited and deformed formations obvious today. The uplifted terraces shown in Figure 3.2 lead to the belief that the area surrounding the Franklin Mountains was of low relief.

Peneplanation of the Sacramento Mountains is revealed by the thin Triassic strata exposed north of the Sacramento Mountains in the Sierra Blanca area (Pray,

1961). Only pockets of the Triassic strata survive in the Sacramento Mountains though the formations extend at least 225 km east (Pray, 1961). The Tertiary brought dikes and sills probably associated with Sierra Blanca intruded along joints (Pray, 1961). Quaternary age deposits occur in the Tularosa Basin to the west and within the mountain block itself. Most of the Quaternary deposits are Santa Fe Group (Pray, 1961).

Lindsay and others (1992) proposed that the Alvarado Ridge was the recharge area for the Artesia Group that supplied Permian Basin aquifers east of the Ridge. Freshwater brought microbes to the formations within the Artesia Group thus producing H_2S . Oxygen from meteoric sources was introduced into the system (DuChene, 2013). The oxygen combined with the H_2S and produced the sulfuric acid.

The timing of uplift of the Guadalupe, San Andres, Sacramento and Franklin Mountains suggests that most of the denudation is tectonic as indicated by the flexure of surfaces, topography and gravity data in this report. This deformation can be dated to the last 20 Ma, and probably to the last 15 Ma based on the cave dates in the Guadalupe Mountains.

CONCLUSIONS

The comparison of uplift of the Franklin, Guadalupe, Sacramento, and San Andres Mountains shows that tectonism largely shaped the topography of the ranges. The three mountain ranges protrude between 325 and 1000 m above the long wavelength topographic high.

Uplift of the terraces that flank the Franklin Mountains showed a tectonic

connection between the topography and regional uplift believed to have occurred in the last 5 Ma. (Armour, 2014; Chapter 2 of this dissertation). Uplift of the Guadalupe Mountains is shown through the progression of cave development and uplift. The oldest cave is dated by K-Ar dating of alunite at about 11 Ma. AFT dates also suggest that burial of the range crests was not below the partial annealing zone of the fission tracks and that uplift has occurred in the last 20 Ma (Kelley and Chapin, 1997).

This study supports the concept that mountain uplift largely created the topography of the southern Rio Grande Rift. Roy and others (1999) and Brown & Phillips (1999) have suggested similar topographic highs from flexural uplift of the Sacramento Mountains.

The concept that erosion is relatively minor in shaping local topography has been proposed by House and others (2003). The implications of this study, in conjunction with Roy and others (1999), and Brown & Phillips (1999), Kelley and Chapin (1997), and House and others (2003) is that the local topography of the Rio Grande Rift reflects Neogene Tectonism and not differential erosion of the rift flank mountains.

APPENDIX Raw GPS Data

Data were gathered in UTM, Zone 13.

Data for the La Mesa Surface in New Mexico is best plotted north to south. This is the control because there is little deformation along that side of the river.

The Robledo Mountains also plot north-south.

The remaining readings are best plotted easting against elevation. The data have been arranged from the southern end of the Franklin Mountains to Fillmore Gap on the north end of the mountains. Data from adjacent terraces have a single space between them. Data from opposite sides of the mountain have double spaces between them.

See Figure 3.2 for an index to the locations of Scenic Drive/Point, McKelligon Canyon, Vinton Canyon, NM 404 is Anthony Gap, and Fillmore Gap/Ft. Bliss gate are the most northerly points associated with the Franklin Mountains.

VITA

Linda Kay Armour was graduated from a central Kansas high school then earned a BA in geography at the University of Oklahoma in 1967. She taught grade school in San Antonio from 1970 – 1973. The family moved to New York where she pursued additional teacher certifications in geography and in earth science. Upon return to Texas in 1981, she taught junior high prior to moving to Midland to work as draftsman for Gulf Oil Company.

She completed her BS in geology at The University of Texas of the Permian Basin (UTPB) in 1988. She promised her daughters she'd not begin her MS in geology until they graduated from high school. The MS was completed in 2001 from UTPB.

After completing her MS in geology, she served as research geologist for a Department of Energy geothermal study with Dr. Richard Erdlac, Jr. She developed the database and oversaw student help. Several publications developed from the geothermal project.

Dr. Armour is retired. She decided to return to school for a PhD in the branch of geology that enticed her into the discipline for the pleasure of attending school and challenge of obtaining the degree. She expects to return to the petroleum industry as a consultant after her return to Midland. She holds Texas Professional Geology License #490.

In addition to teaching and work as a draftsman, Dr. Armour has worked as geological technician, environmental technician, and assistant geologist for Chevron, Phillips, Conoco, Mobil, Pure, a few independent and small petroleum companies, and the Center for Energy and Economic Diversification, the community service branch of

UTPB. All of these positions have been in Midland, TX or Hobbs, NM. She claims three discoveries. Additional publications include poster sessions at Geological Society of America meetings.
