Acknowledgements

I would like to acknowledge everyone whose work made this project possible: first and foremost my advisor and cSETR director, Dr. Ahsan Choudhuri for giving me this invaluable opportunity, Nate Robinson for his kind guidance and support, and all the team members that ever contributed to this project, specially Robert Ellis, Gabriel Trujillo, Luis Sanchez, Juan Barragan, Christopher Navarro, and Jesus Flores. Finally, I would like to extend my gratitude to NASA for supporting this research venture and to LSAMP's Bridge to the Doctorate Program for generously funding my graduate studies.

Abstract

The Center for Space Exploration Technology Research (cSETR) has developed a set of shear coaxial injectors as part of a system-level approach to study LOX/CH₄ combustion. This thesis describes the experimental studies involved in the characterization of the effects produced by two design injection face plate variables: post thickness and recession length. A testing program was developed to study the injectors' atomization process using LN₂ as a substitute for LOX in cold flow and the flame anchoring mechanisms in hot firings. The cold flow testing stage was conducted to obtain liquid core measurements and compare its behavior between the different geometric configurations. Shadowgraph technique was used during this testing stage to obtain these measurements and compare them to previously published data and core length mathematical models. The inlet conditions were selected to obtain mixture ratios in the 2-4 range and a wide range of high momentum flux ratios (30-150). Particle Image Velocimetry (PIV) was also used in the testing of the three injectors to assess their atomization performance and their fragmentation behaviors. Results show that changes in central post thickness and co-annular orifice recession length with respect to the injection plate have quantifiable effects in the generated spray flow field, despite not being accounted for in traditional break up calculations. The observations and results of this investigation lead to a proof of concept demonstration in a combustion setting to support the study of flame anchoring mechanisms, also discussed in this work.

Chapter 1 : Introduction

1.1 Background

The work presented in this thesis is part of an applied propulsion research and education program at the Center for Space Exploration Technology Research (cSETR), a NASA University Research Center, at The University of Texas at El Paso. Among the goals of this research center, is to produce a body of research that will benefit the characterization of methane as a low-toxicity alternative propellant for aerospace and propulsion applications. The selection of this propellant stems from the fact that, even though LOX/CH₄ maintains the energy density levels characteristic of bipropellant systems and features the highest vacuum specific impulse for hydrocarbons, the development of flight hardware specific to it has lagged¹. Benefits in mass allocation and compatibility with liquid oxygen's cryogenic storage temperature are some of the most notable reasons that have placed methane as a feasible alternative to hydrogen as a fuel for rocket propulsion. Additionally, if considered against hypergolic propellants, methane offers lower toxicity levels and more simplified safety requirements.

The cSETR has constructed this project and the facilities that support it to the end of advancing the body of knowledge associated with the development of LOX/CH₄ combustion and propulsion technology. The Liquid Oxygen and Hydrocarbons Ignition Physics team was formed to materialize the characterization efforts of LOX/CH₄ combustion by building upon the heritage of systems developed for this bipropellant combination and other theoretical studies and applying them towards the development of a reduced-scale LOX/CH₄ combustion system. The experimental nature of this project's investigative approach has led to the design, development, and integration of a series of components that facilitate the study of the processes leading to the generation of thrust for liquid rocket engines running on LOX/CH₄, namely, the ignition,

injection, and combustion of these propellants. The ignition and injection stages consist of individual subsystems requiring their own hardware development and multi-phase testing programs. Both of these stages are intended to be integrated into a single, modular combustion system to facilitate hot-firing testing and ignition physics studies.

1.2 Project Overview

The spray atomization of the propellants as they are injected into the combustion chamber has been associated with the uniformity and overall quality of the fuel burning process, leading to an interest in the optimization of injector plate geometry. Under the aforementioned efforts at cSETR, a test article set consisting of three uni-element shear coaxial injectors was developed to support the spray atomization studies of LOX/CH₄. The study of two geometric variables led to the design and manufacture of the test articles: liquid post thickness and fuel injection port recession. It is unclear how and to what extent these variables affect the breakup and mixing of propellants. All three injectors were submitted to an identical testing program in order to establish a comparison between the fluid dynamics observed in each case. The arrival to a conclusion as to which configuration produces the most desirable spray characteristics would move forward the design optimization of LOX/CH₄ injection hardware.

Testing was conducted at the Goddard Propulsion Laboratory located in the University of Texas at El Paso in two major phases: cold flow testing and hot-firing testing. The former focused on placing methane and the injection hardware in the context of spray atomization literature to assess the translatability of previous studies conducted for other propellants and hardware configurations to those developed at cSETR. The latter phase sought to contribute experimental knowledge in LOX/CH₄ flame dynamics and ignition physics, while validating each individual component as a technology demonstration.

1.2.1 Problem Statement

A combination of thorough numerical and experimental studies of the combustion and injection processes associated with any propellant is essential to obtain a solid understanding of its behavior and, therefore, its implementation in rocket engine design. The problem to address is the scarcity of experimental knowledge of the effect of certain geometric variables in the shear coaxial injection, one of the simplest and widely used injection configurations, of LOX/CH₄. Previous experimental studies have reportedly used heritage hardware that has been developed for other propellant combinations without certainty of the extent to which projections of propellant behavior translate to LOX/CH₄. Various sources cite the importance, albeit at different degrees, of parameters such as J, We, and Oh numbers, but in most cases, these parameters do not address the sizing differences in the annular fuel injection ports, the thickness of the LOX post, and the presence of a recession with respect of the injector face plate. These geometric constraints have not been discussed at length although they have a direct effect liquid core/ gas film interaction and, therefore, on the jet breakup.

Furthermore, the interaction observed during combustion between the injector's atomized fluid jet and the ignition source's propellant stream has left another gap of knowledge to be explored. Documented numerical analysis and computational simulations of this and the atomization process would benefit from experimental validation of projected fluid dynamics in LOX/CH₄ shear coaxial injectors.

1.2.2 Thesis Scope

The sub-system relevant to this thesis is the injection system responsible of introducing the propellants onto the combustion chamber. This thesis seeks to describe the experimental studies associated with the atomization of methane and the spray diagnostics used to complete

the test program of cSETR's injection hardware. Brief discussions of the test article's design and the relevance and progress of this subject in the scientific community are included. This work focuses on the fluid dynamics produced by the injector configurations developed for this project and the implications of the injector plate geometry changes. This thesis also discusses the methodology followed during the test article set's testing program, the results obtained from these experiments, and its integration as a fundamental component of the system level testing of a LOX/CH₄ combustion system.

1.2.3 Objectives

The objectives of the spray atomization studies featured in this thesis are the following:

1. Characterize cSETR's injection test article set in a manner that the effects of its design variables are understood and applicable to subsequent designs. This entails the study of the liquid jet's structure in a cold flow setting.
2. Complete an injection test program that uses methane as a propellant and allows the comparison of the observed atomization performance with that documented for hydrogen.
3. Support the system level testing of cSETR's LOX/CH₄ combustion system, while increasing the understanding of the injectors design's effect on the combustion process. This will allow for the analysis of the flame front propagation inside a combustion chamber for the three plate injector geometries developed at cSETR.

Chapter 2 : Literature Review

2.1 LOX/CH₄ in Rocket Propulsion

The benefits of adopting methane as an alternative fuel for liquid rocket engines are not only one of the driving reasons for this project but also the cause of a renewed interest in developing LOX/CH₄ hardware. In 2009, the company Aerojet published the results of the 870 lbf (3.87 kN) testing of an LOX/LCH₄ engine and torch igniter, citing the dearth of “serious development” for this propellant combination since the 1960s². The hardware assembly used for this testing program was a modified residual from the Aerojet Kistler Program, which was developed for oxygen/ethanol testing. The observed combustion process described in this paper is described as consistently stable in a Pc range of 111-190 psia. The company also demonstrated the ability to operate with methane as it transitioned from a two-phase fluid during startup to a sub-cooled liquid-liquid steady state. As a film coolant, methane was shown to be less effective. However, high combustion performance and reliable spark ignition using LOX/LCH₄ was deemed achievable.

NASA Johnson Space Center’s Morpheus Project has been developing an autonomous, reusable, rocket-powered Vertical Takeoff/ Vertical Landing vehicle for lunar precision landing since 2010³. The project intended this to be a “green” propellant lander, leading to the selection of having a LOX/CH₄ propulsion system. The availability, safety, compatibility, and potential in-situ utilization of LOX/CH₄ are cited as some of the reasons for this bi-propellant system’s technology maturation. Operating as a blow down system, the main engine has a throttleable, film-cooled design and the ability to produce up to 4300 lbf (19.13 kN). Its reaction control system is also devised as a LOX/CH₄ propulsion system. JSC has collaborated and overseen cSETR’s methane characterization studies.

A partnership of European and Russian industries has also initiated technological campaigns for LOX/CH₄ concepts. The project VOLGA was presented in 2002, and it seeks to undergo experimental and theoretical activities to develop this propellant combination primarily for large liquid reusable booster applications⁴. The result of this venture has been the outline of technical targets for an engine, from which a thrust range of 4000 kN, an MR of 3.5, and an I_{sp} of 320s at sea level can be highlighted. This development has also surfaced methane's improvements over kerosene regarding the ecological behavior of the combustion byproducts and combustion stability, among others⁵. More recently, the American aerospace company SpaceX began the discussion in 2009 of Raptor, a reusable staged methane-fueled rocket engine concept. The development of this concept has been associated with Mars exploration and its facilitating its testing is expected to require significant enhancements to be made to NASA's Stennis testing facilities⁶.

2.2 Shear Coaxial Injection

In the early 1990s, the method for determining the operational region of cryogenic coaxial injector was known as hydrogen temperature ramping. It consisted on inducing a spontaneous instability by hot firing a set of injectors in a combustion chamber. However, the spray parameters involved in the presence or absence of combustion instabilities were not well understood. When showing the effect of propellant injection temperature in a 20,000 lbf_f LOX/LH₂ rocket engine, Wanhainen, Parish, and Conrad showed that rather than due to hydrogen temperature variations, observed instability was due to the velocity ratio of the injected liquid and gas. This premise led others to infer that a decline in droplet burning efficiency was a probable cause and triggered investigations of the fluid dynamics involved in the liquid and gas velocities' interaction. One of the most significant contributions in the field of coaxial injection

and atomization was authored by investigators of the Pennsylvania State University. Their studies focused on injector response, recirculation zone formation, and droplet characteristics and were conducted using mixtures of water/air and LN_2/GN_2 to simulate liquid oxygen and gaseous fuel interaction. Kaltz et.al used a shear coaxial injector showcasing a 0.1 in (2.54mm) recession length in the central post. An analytical model suggested that at certain frequencies, the injector response may become unstable after the fuel temperature decreases to a certain point. Preliminary LVD measurements suggested the formation of a recirculation zone, which was yet to be sized. A Phase Doppler Particle Analyzer system was not able to operate and measure droplet parameters in full-flow velocities during LN_2/GN_2 due to the formation a dense spray⁷.

2.3 LOX/ H_2 Sprays and Combustion

The study conducted by Woodward et.al is relevant to cSETR's experimental injection system characterization since, like the cold flow experiments described in this thesis, the testing conducted by Woodward was done with an unignited mixture and analyzed with shadowgraph techniques, except that the propellants used were LOX/ GH_2 . The main purpose of that investigation was to verify that the classical breakup profile for shear coaxial injectors (the presence of an intact core breaking up into ligaments and eventually into atomized droplets in the downstream region) was still true for momentum flux ratios that lie beyond the already demonstrated 1-5 range⁸. Several tests at high momentum flux ratios (20-150) were conducted with a shear coaxial LOX/ GH_2 injector and it was found that the LOX core presented a sinusoidal behavior that eventually stayed true to the classical breakup profile. The investigators used a strobe-lit system and reported that no droplets were visible from the acquired images. Some uncertainty and lost visual data occurred from window damage, low spatial resolution, and a gap between windows of visual access. Core length measurements were compared to various

mathematical models developed for non-combustion conditions with the purpose of determining their applicability in real rocket engine design. A total of nine models were made available to compare observed core lengths, but only the projections by Woodward et.al, Davis's two-phase subcritical, and Eroglu et.al were not under-predicted by at least an order of magnitude.

Figure 2-1 Plot of LOX core length measurements from Woodward's study as well as those from Boniface and Reeb against gas-to-liquid J

2.4 LOX/CH₄ Spray Diagnostics

Both numerical and experimental studies are important aspect of a propellant's characterization process. The following are some of the studies from which the project outlined by cSETR for LOX/CH₄ spray and atomization has been building from.

2.4.1 Numerical Studies and Simulations

Three-dimensional simulations are one of the means of improving the understanding of combustion dynamics. A work published by Huo and Yang in 2011 describes the flame stabilization mechanisms of LOX/CH₄ at supercritical conditions for a shear coaxial injector. The injector geometry is also referred as "typical" and was meant to match that of a previously

published experimental study and consisted on a central LOX stream separated from the co-flowing gaseous methane by a 0.38mm LOX post. Two and three-dimensional Large-Eddy Simulations (LES) were performed for supercritical pressures considering a laminar flamelet model and a flamelet/progress-variable approach. In combustion conditions, formation of primary and secondary flames was observed. Overall, strong 3D flow structures dominated the mixing and combustion processes, and the flame appeared to follow the ligaments of oxygen being shed from the liquid jet¹. The investigators observed that the flame consistently anchored in the recirculation zone after a splitter plate confirming known LOX/CH₄ mechanisms.

Earlier, in 2009 the results of a numerical study of LOX/CH₄ spray mixing and combustion at supercritical conditions were published by the University of Salento, Italy. Their work consisted of property calculation and CFD simulation of these processes in shear coaxial injectors. The authors argued that combustion knowledge in methane could not be directly transferred to methane technology because at typical injection conditions, hydrogen and methane exhibit fundamental differences: hydrogen is far in the supercritical region while methane is near critical. Also, hydrogen exhibits a behavior resembling of ideal gas while some of methane properties' behavior deviates significantly from it⁹. The density and isobaric specific heat was plotted for oxygen and methane as functions of temperatures using NIST data, ideal gas formulations, the Soave-Redlich-Kwong (SRK) equation of state, and the Peng-Robinson Equation of state. The simulation process began with cold flow conditions, and from these solutions, combustion and reactive scenarios were modeled. The geometry used for these simulation was described as being that of a "typical methane-oxygen shear coaxial injector". In four simulated cases using NIST and SRK models, discrepancies in predicted core length were observed. Furthermore, the activation of turbulence model LES showed eddy formations in the

oxidizer/fuel interface and small instability waves immediately downstream of the injector. Although these observations establish a prediction baseline, the authors conclude that in the case of supercritical combustion of LOX/CH₄, the conditions could not be presently and accurately predicted by commercial CFD codes.

2.4.2 Experimental Development

The combustion of LOX/CH₄ was investigated experimentally by the German Aerospace Center DLR Lampoldshausen by developing a micro-combustor equipped with optical access and a uni-element shear coaxial injector¹⁰. This combustor served as an inspiration to cSETR's MOAC (Multi-Purpose Optically Accessible Combustor) and its associated injection system. The spray diagnostics used at DLR Lampoldshausen for this development program were Schlieren photography and OH-radical visualization, both with the capability to reach frame rates of up to several tens of kHz. The investigation covered an approximate J range of 0.2- 2.5 in hot firing tests and compared the breakup length of LOX/CH₄ and LOX/H₂. The findings suggest that the general break-up behavior of both fuels as a function of J has similar tendencies. However, the authors conclude that in order to scale LOX/H₂ hardware for methane-fueled propulsion systems, the interaction between combustion and atomization must be explored in addition to characterizing the fluid dynamics of the spray with non-dimensional parameters.

In 2009, an experimental study of a full-scale swirl coaxial injector designed to study combustion instabilities for LOX/LCH₄ was published by the University of Alabama in Huntsville. The study consisted of conducting cold flow tests at ambient back pressure using filtered and deionized tap water. The actual design of the injector was reportedly developed in accordance to “classical swirl injector design parameters”¹¹. The flow rates were varied and their spraying behavior analyzed with backlit and stroboscopic systems, as well as with a Phase

Doppler Particle Analyzer. The study focused on obtaining free cone spray angles and the droplets' Sauter mean diameters as a function of their radial position with respect to the center of the spray. It was found that variances in mass flow rate produced changes in droplet size and velocity but had a negligible effect in free cone spray angle. Eberhart and his collaborators concluded that the viscosity and surface tension of water were dissimilar to those of LOX to the point of impeding an accurate assessment of the true quality of the atomization for its final application. The authors expressed interest in conducting future studies with liquid and gaseous co-flow in the fuel annulus that allow studying the effects of post recess length.

Salgues et al. from Pennsylvania State University experimentally compared two single element swirl coaxial injectors to a shear coaxial injector using LOX/GCH₄ as propellants under repeated conditions¹². Of the two swirl injectors, one was designed to have a higher fuel velocity than the other. The experimental study targeted a MR of 3 at a Pc of 4 bar. The optical diagnostics used to analyze the liquid core breakup profile and flame structure produced for each test article were OH Planar Laser Induced Fluorescence (OH-PLIF), OH* chemiluminescence, laser light scattering and shadowgraph imaging. The velocity ratio of propellants was a major parameter to describe atomization quality, and from it, parameters such as Weber Number, Momentum Ratio, and Momentum Flux ratio were calculated. The Weber number was calculated to be 65,400 and 8,400 for the swirl injectors, and 438, 293 for the shear coaxial injector. It was observed that the swirl injector produced a liquid sheet that exited the LOX post as a radially expanding hollow cone. This motion created more contact area with the high speed methane, which in turn improved the atomization quality. On the other hand, the shear coaxial maintained a somewhat unaffected liquid jet until further downstream of the combustion chamber. In a combustion scenario, higher injector efficiencies were observed to hold an OH-PLIF signal is

closer to the injector face, with decreasing efficiency signifying a dispersion from the injector centerline.

Figure 2-2 Visual representations in Salgues et.al shear coaxial injection studies

It should be noted that the investigators experienced difficulty in igniting LOX/GCH₄ mixtures and comparisons between instantaneous chemiluminescence and OH-PLIF signal position could not be made to determine whether an inner flame front close to the evaporating LOX core existed, since disagreements in the visual data suggested it. Finally, combustion was detected away from the chamber's center, possibly due to the recirculation of unburned methane. The burning of the fuel in such unfocused areas is associated with a decrease in combustion efficiency and has been reported as an issue with LOX/CH₄ combustion. A comparison of the shear coaxial injector geometries of this and other studies can be found in Appendix A.

Chapter 3 : Technical Approach

In liquid bipropellant rocket engines, the design of the injector has a direct effect on how smooth and stable the combustion inside the rocket's chamber is. To prevent destructive surges in the combustion chamber, it is desirable that no unburned propellant is accumulated before its injection. A method to prevent this sort of accumulation is to provide even and effective mixing of the propellants, a key factor in injection hardware design¹³. The quality of the mixing process relates to the configuration of the injector face plate, which must be selected with other design parameters in mind, such as: local MRs, structural integrity during operation, and injector orifice size, a variable affecting droplet size.

3.1 Test Article Description

The shear coaxial type injector is used in gaseous fuel/liquid oxidizer type applications, and its defining feature is the presence of two concentric orifices. Its operation consists of flowing a jet of liquid oxidizer that, upon exiting the injector face plate, comes in contact with the fuel in a gaseous state, exiting from a surrounding annular port, and travelling at a speed that is at least one order of magnitude higher than the oxidizer's velocity. The difference in the oxidizer and fuel velocities produce a surface instability between the fluids and a shearing effect responsible for droplet formation. The traditional atomization profile observed in shear coaxial injection involves the formation of a relatively short liquid core in the central fluid. The droplets formed in its vicinity signify mixing level of the propellants, which is a factor that affects the amount of available surface area for burning.

The major factor driving the body size and design of the single injection element test article was its interface with the combustion chamber. The interface had to possess the feature of

modularity to enable the test articles to be exchanged with relative ease while maintaining the integrity of the equipment. The assembly and major design features of the test article are discussed in this section.

Figure 3-1 Permanent cSETR injection test article assembly

3.1.1 Shear Coaxial Injector Set

The injector in use is assembled in such a way that its face plate is aligned with the combustion chamber wall containing the allocated circumference. The allowed circumference has a 50 mm diameter and is intended to accommodate any injection device conforming to this constraint. During assembly, the injector is introduced into this circular space from the inside of the combustion chamber. Once the selected injector is in place, a retainer is aligned from the opposite side of this wall and bolted to the combustion chamber with a series of Allen head screws. When conducting any type of testing requiring the pressurization of the combustion chamber, RTV silicon is applied to the back of the injector face to ensure proper sealing of the test article.

Each injector consists of a unified body that already permanently holds the fuel and oxidizer ports and gas manifold in place by the use of welding and brazing techniques. This

leaves only the need of two ¼” FNPT ports to connect to the propellant feed system. The oxidizer pathway flows directly and lengthwise across the injector body’s center starting from the rear. The fuel pathway, on the other hand, begins at a port located on the side that feeds perpendicularly to the oxidizer. The gaseous fuel is fed onto an internal manifold chamber that surrounds the LOX post and allows the gas to be released annularly at a uniform pressure and velocity.

The injectors are labeled as A, B and C for testing purposes and each is identical to the others in all respects except for one variable in the face plate injection orifices geometry. The sizing of the injection area and port diameters was completed using the following equations developed by Huzel and Huang. The design process assumed a 20% pressure drop across the injector and a K value of 1.5¹⁴.

$$A_{Inj} = \dot{W} \sqrt{\frac{2.238K}{\rho \Delta P}} \quad d_{orifice} = \left(\frac{3.627K \dot{W}^2}{\rho \Delta P N^2} \right)^{0.25}$$

In all three injectors the face plate orifices have the exact same injection areas: 3.14 mm² in the central liquid orifices and 2.84 mm² in the annular gas orifices. The central liquid orifice in all cases has a diameter of 2 mm (0.0787 in). Each of the injectors has been labeled according to the variations in their face plate and can be explained as follows:

Injector A: Baseline design, with a fuel outer annulus diameter of 5.2 mm and liquid post thickness (τ_θ) of 1.42 mm.

Injector B: the liquid post thickness τ_θ is increased to a value of 2.26 mm, resulting in a thinner film of surrounding gas during atomization.

Injector C: a recession length τ_L of 5 mm with respect to the face plate is added, sinking the LOX post and otherwise retaining the same geometrical configuration as injector A. Introducing a

recession with respect to the injection plate surface results in the brief mixing of the fluids prior to their complete exit from the injector's body.

Figure 3-2 Geometric variables in cross sectional areas of shear coaxial injection face plates, from left to right: Injector A, B and C

Spray Parameters

The evaluation of the following parameters is an important aspect of the description of shear coaxial injection:

(1) Momentum Flux Ratio: $J = \frac{\rho_G U_L^2}{\rho_L U_L^2}$

(2) Weber number: $We = \frac{(U_G - U_L)^2 \rho_G D_L}{\sigma}$

(3) Ohnesorge number: $Oh = \frac{\mu_L}{(\rho_L \sigma D_L)^{\frac{1}{2}}}$

, where U_G is the velocity of the gaseous fluid at the outlet and U_L is the velocity of the outgoing liquid jet.

These parameters can be experimentally calculated from the injection test articles' orifice geometry and the inlet flow conditions, thereby allowing the analysis of the resulting spray atomization process. The first parameter, J , is a specification used in liquid rocket engines that

use coaxial injection, which typically have a momentum flux ratio that falls in a range of 2 to 11⁸.

It is of paramount importance to note that for a given inlet condition (a set of liquid/gas mass flow rates) these three parameters will have identical magnitudes for the three test articles. This will be true as long as the fluid properties are consistent, since the liquid orifice diameter is the same for all injectors, as is the fuel injection orifice areas. The hypothesis at this stage of the project is that the geometric variations present in the test articles, which are unaccounted for in these parameters, will produce visually discernible changes in the spray profile observed by each test article. If this is proven to be true and these changes can be quantified as different mass flow rates are tested, the geometric variable producing the most favorable break-up profile could be adopted to develop future, optimized iterations of this type of injection hardware.

3.1.2 Combustion System and Testing Facilities Overview

The following are the other major components of this experimental program. Each of them was developed and validated individually and played a major role at some point of the injector set's characterization.

Multipurpose Optically Accessible Combustor (MOAC)

The Multipurpose Optically Accessible Combustor (MOAC) is a small-scale combustion chamber that has the ability to produce 71 N of thrust and sustain an I_{sp} of 368 s for up to 30 seconds using LOX/LCH₄. The total combustion volume is 80x80x150mm and the throat of the converging section located at one of its ends has a diameter of 6mm. The chamber was manufactured from Stainless Steel 304 with a wall thickness of 4.2 cm. The maximum allowable pressure and temperature have been rated as 290 psia (2MPa) and 3000K respectively, but it is recommended that these levels are not sustained for periods of time exceeding 20-30 seconds.

Figure 3-3 MOAC cross sectional area and components

The optical access is granted by four fused quartz windows, each with a thickness of 3.5 cm. Two large windows are positioned to comprise the area of combustion and two smaller ones are intended as access points for a laser sheet or other optical diagnostics. The large windows are secured by mounting brackets secured with 20 m5 SS 316 hex head bolts, while the mounting brackets for the smaller windows are secured with 10 m3 SS 316 hex head bolts. Modularity is an important feature of the MOAC, since it houses the injector and allows for its simple removal and replacement like that as well as for other instrumentation's. Several ports are built into the MOAC to facilitate the installation of temperature and pressure instrumentation. One of these, a NPT port is used for the interface with the torch ignition system.

The internal pressure created during operation adds a self-sealing capability to the chamber, but other measures must be taken to ensure proper sealing. Pieces of alumina silica gasket are cut to match the interfacing metal-to-metal surfaces of the window mounting brackets. Additionally, RTV silicone is applied to the edges when anticipating high chamber pressures and left to cure once the assembly has been prepared for testing.

Swirl Torch Igniter

The swirl torch igniter is the ignition source developed in house for this project. It has undergone an iterative process to empirically improve the reliability and range of ignition. The torch ignition system houses an internal swirl that triggers the mixing of propellants by the momentum of colliding injections. The oxidizer flows down the main channel and interacts with four tangential methane inlets that form a swirl that causes the mixing of the propellants prior to ignition. The injection distance (the distance that the oxidizer flows until coming in contact with the fuel) was increased from 1/4" to 1"¹⁵. The latest iteration of the torch igniter consists of a unified body containing both oxidizer and fuel injection manifolds. The mixed propellants are then ignited using via spark ignition. This consists of a tungsten lead surrounded by silica ceramic that supports an electrical arc. The arching is initiated by a 25 kV step up transformer.

Figure 3-4 Ignition source: swirl torch igniter

Facilities and Other Capabilities

The cryogenic delivery system used for combustion experiments is located inside a blast-proof bunker inside the Goddard Propulsion Laboratory. The delivery pipeline network consists of two main lines, one for the oxidizer and one for the fuel, and each counts with its own pre-chill and purge branch. The delivery lines are made of high purity 304 Stainless Steel to ensure compatibility with LOX, and they are supported by a stainless steel L-bar structure. The size of

the delivery lines was selected to limit the Reynolds number to be less than 2000 as a means to reduce detonation risks in the liquid oxygen line and control heat losses. The lines feed into the combustion test article, which may be set up in an atmospheric conditions test stand or inside a vacuum chamber, also known as a Multipurpose Altitude Simulation System (MASS). A set of Kevlar panels separate the cryogenic storage tanks from the experimental setup to protect the hardware in case of an outburst in the tanks.

The logistics of the experiments are ultimately controlled remotely from a room adjacent to the bunker by the manipulation of a Graphical User Interface (GUI) created with LabView. The programming of the PCI cards is performed using National Instrument's DAQ Assistant tool. The data acquisition process is achieved by the channeling of the instrumentation wires to an excitation signal and a data sampling module. The program and its graphical interface allow the user to configure running times during the tests, select a stopping mode (manual, automatic, or emergency), and command the actuator valves through an array of solid state relays. The wiring of the DARCS is present inside the bunker to couple with two main categories of components: controlling and metering devices. The controlling connections allow for the activation and deactivation of one or more components represented in the patch panel in either side of the system, while the metering components feed the response to the display monitors in the control room. Also, the experiments can be remotely monitored and recorded by a four channel Digital Video Recording (DVR) system.

Figure 3-5 Blast-proof facilities at UTEP's Goddard Laboratory

A similar interface between propellant delivery system, controls, and data acquisition system exists for experiments mounted outside of the bunker, such as the cold flow test not requiring blast-proof protection. The deliver-controls interface will have a different scale and configuration according to the needs of the specific tests, and each flow schematic with its respective GUI will be outlined for each test matrix.

3.2 Combustion System Demonstration

The integrated combustion system was assembled and tested in the Spring 2012 term in a hot firing setting to assess its functionality and performance. The first iteration of the swirl torch igniter and one of the shear coaxial injector were assembled onto the MOAC and fed with the cryogenic delivery system installed at the Goddard Laboratory's blast-proof bunker.

Figure 3-6 MOAC assembly prior to shakedown testing

Two different shakedown tests were performed. The first test consisted of running air and gaseous methane at an O/F ratio of 17.3. Poor mixing and flame blowout were major issues to address when controlling the injection velocity of both gaseous fluids, since the shear coaxial injector is designed for co-flowing liquid and gas. In the end, the mixture was successfully ignited, and the MOAC proved the ability to contain the flame and byproducts while allowing this process to be recorded through its windows. The second test consisted of running a gaseous oxygen and methane mixture at an MR of 3.5. Several runs were made to progress the MR to an O_2/CH_4 stoichiometric value of 4.0 with volumetric flow rates of 42 LPM for oxygen and 56 LPM for methane. The range of injection pressures was 40-50 psi, and the duration of the firings was limited to 25 seconds in all cases. The MOAC was able to withstand and support these conditions as well. Hard ignitions were observed when the order in which the propellants were introduced was not the appropriate one; specifically, when methane was injected first to avoid blowouts of the torch igniter flame with the oxygen flow. Adjustments in pressures and flow

rates were made to allow both propellants to be injected simultaneously, but the torch igniter had to remain turned on for as long as ignition was needed.

Figure 3-7 Gas-gas hot firing

No damage or crack propagation was observed in the quartz windows post-test. However, disassembling the large windows from the MOAC posed some difficulties due to the thermal expansion of the chamber. This problem can be mitigated with pre-sanding of the windows and ensuring proper sizing during assembly.

3.3 Cold Flow Testing

Cold flow testing is often used to improve the understanding of the fluids' behavior prior to hot-firing a specimen. The characterization of injectors used to support LOX/CH₄ testing has not been an exception. For example, the testing of Aerojet's modified platelet injector involved cold flow tests of the hardware with water to verify injection uniformity and determine hydraulic resistance². The value of these studies lies in that the injection process is isolated from the chemical reactions present during combustion.

In this project's cold flow testing stage, the purpose was to obtain a general idea of the behavioral tendencies of the propellants as they were injected out of each of the test articles. The

cold flow tests involved the computation of spray parameters and the integration of flow visualization techniques. Ranges of mass flow rates, temperatures, and pressures were laid out to establish a framework for the project.

3.3.1 Methodology

A test matrix was designed to compare the behavior of propellants as they are injected onto a slightly pressurized ($P_c \sim 17$ psia) combustion chamber in cold flow through different injector geometries. Initially, the main success criterion of the cold flow testing was simply that enough high quality images were collected to determine which of the three injectors produces the best atomization. A large test matrix consisting of a MR range of 1-8 was laid out as well as retesting sessions with gradual increments in chamber pressure. However, after completing preliminary runs at low and high mixture ratios and consultation sessions, it was determined that a MR range of 2-4 produced the observations that were the most relevant and valuable to the injector characterization discussion. Chamber pressure is not only a variable that is not involved in the computation of spray parameters, it also proved to have negligible effects in tests conducted at other testing facilities whose pressurization capabilities exceeded those of the Goddard Propulsion Laboratory. Therefore, the high pressure tests were suspended, and the runs lying outside of the newly narrowed MR range were discarded. During the test planning phase, it was decided that quantitative data was attainable with the available flow visualization systems and that a more complete assessment of the flow field would be completed.

The selection process of the propellants to be used in the cold flow took into consideration two main factors: similarity of the fluid properties involved in LOX/GCH₄ interaction and safety of the system operation. Using gaseous methane as the fuel injected through the annular orifice was a logical choice for characterization purposes. There were several

candidates for the central liquid fluid as there was precedence for using water, liquid nitrogen, and liquid oxygen in this type of tests. Due to safety issues and to enable the testing to be conducted outside of the blast-proof facilities as to not conflict with other projects' testing schedules, LOX was no longer a feasible option. A study comparing the behavior of the properties relevant during breakup (density, surface tension) in their cryogenic state was performed for LN₂ and LOX. Based on the comparison, LN₂ was selected as a substitute to LOX during cold flow testing. The properties were plotted for the entirety of the pressure ranges that could be expected during operation.

Figure 3-8 LN₂ and LOX properties comparison

Cold flow testing was conducted in an atmospheric aluminum rig at the Goddard Laboratory. The same inlet conditions were targeted for each injector to cover the same mixture ratio and momentum flux ratio ranges and establish a comparison between the test articles. Optical diagnostics will be put in place to record the breakup process and assess the findings post-test. A detailed description of the test matrix and the flow visualization systems follows.

Test Matrix

The mixture ratio range (2-4) was selected to resemble the burning O/F ratios of typical methane engines and the values near the stoichiometric O/F ratio. The tests were also developed to study a momentum flux ratio range that lies above what are considered to be high J values, since it has been suggested that the spraying process would be identified near the injection plate¹⁶. A total of four different MR values were tested with the addition of a LN₂-only run to assess the jet without the shearing effect. Targeted values for mass flow rates, mixture ratios and J are shown in Table 3.1.

Table 3-1 Final cold flow test matrix

Case #	GCH4 Mass Flow rate, kg/s (lbm/s)	LN2 Mass Flow rate, kg/s (lbm/s)	MR	Vr= U _G /U _L	J= ($\rho_G U_G^2$) / ($\rho_L U_L^2$)
0	0	0.01±0.002 (0.022±0.004)	∞	-	-
1	0.0025±0.005 (0.0055±0.011)	0.01±0.002 (0.022±0.004)	~4.0	105	30
2	0.0028±0.005 (0.0066±0.011)	0.01±0.002 (0.022±0.004)	~3.5	120	45
3	0.0035±0.005 (0.0077±0.011)	0.01±0.002 (0.022±0.004)	~3.0	145	55
4	0.0045±0.005 (0.0099±0.011)	0.01±0.002 (0.022±0.004)	~2.0	230	150

In the inert mixture, the LN2 flow rate was meant to be kept constant while the methane flow rate was varied to test the different mixture ratios. The maintenance of the flow rates was

achieved by setting the tank pressures beforehand and ensuring that the desired flow rate would be outputted.

In order to calculate these targeted values, the fluid properties that would be actually observed during the experiments had to be predicted. The surface tension of the liquid nitrogen was taken to be 0.004N/m, for instance. With targeted mass flow rates and velocities, a prediction of the spray parameters was also possible as seen in the case of momentum flux ratios in the above table. The Oh number, which described only the liquid core for a given condition was calculated to be approximately 0.0014. In the case of We numbers, the expected values were plotted with respect to MR.

Figure 3-9 Predicted We number behavior with varying MR values

Core length analysis

The core length is a parameter that has been used in previous experimental studies to study and develop liquid core fragmentation models. This parameter is obtained by normalizing the jet breakup length measurements and normalizing them by the central liquid core diameter, which in this project is 2 mm. The core breakup length was one of the most significant outputs of the cold flow tests and it was obtained with the shadowgraph technique visualization.

A comparison between core fragmentation models and measured values in this study is needed to correlate the obtained results with existing literature on jet core length analysis. From the fragmentation models discussed in the Literature Review section, two were selected as baseline predictions for the core breakup lengths.

$$\text{Woodward model: } 0.0025 \left(\frac{\rho_G}{\rho_L} \right)^{-0.44} Re_D^{0.76} We_G^{-0.22} \quad (1)$$

$$\text{Davis model: } \frac{25}{J^{-0.2}} \quad (2)$$

The Woodward relation was favored over another very similar model by the same author for its applicability to nitrogen data, which has substituted oxygen as a central fluid in these experiments. Similarly, the Davis model was selected over another of this author's correlations since the above model is applicable to two-phase coaxial jets in subcritical conditions, namely cases where both the ambient and the co-annular fluids are in gaseous state and interacting with a liquid jet⁸.

3.3.2 Experimental Setup

One shear coaxial injector at the time was mounted on the MOAC and operated on an atmospheric aluminum rig. The experiments were conducted with an inert mixture that was exhausted from the combustion chamber onto a venting duct. The three major components of the test setup that enable the collection of data are the propellant delivery system, the LabView data acquisition system that monitors and records the flow properties, and the flow visualization system.

Delivery System

To calculate the mass flow of liquid nitrogen, a cavitating venturi flow meter paired with a differential pressure transducer was installed on the cryogenic delivery line and used as an

orifice. Knowing the dimensions of this venturi as well as the fluid properties and the discharge coefficient, the flow rates for given pressure drops across the venturi can be calculated. The following equation, which is valid for downstream pressures totaling 80% of the upstream pressure readings, is used to calculate volume flow rate.

$$\dot{V} = A_t C_d \sqrt{\frac{2(P_1 - P_2)}{\rho(1 - \beta^4)}}$$

Where $A_t=0.0081\text{cm}^2$, $C_d\sim 0.95$, $\beta=d/D$ and the LN_2 density is evaluated at 200 psia and 110 K. This formula gives accurate volumetric flow rate as long as nitrogen is liquid at both inlets of the differential pressure transducer. This is verified by measuring the downstream temperature to be less than 110K, which ensures there is liquid at the downstream point. After setting a tank pressure, P_1 and P_2 values were recorded to obtain a pressure drop values. The calculated volume flow rates were inputted to obtain a plot and a relationship with mass flow rates in Excel. For ease of calculation in LabView, a simplified curve fit was found relating mass flow rate in kg/s to pressure drop in psia and is shown below. The R^2 value was calculated to be ~ 0.998 .

$$\dot{m} = .0023(\Delta P)^{.5}$$

Gaseous methane flow rates were measured using the readings of a volumetric flow meter. The readings were noted to then be adjusted with pressures set in the methane tank. The change in working fluid is then performed since the instrument is calibrated for nitrogen gas. From a calibration table for several common gases provided in the instrumentation manual, the measured volume flow rate of the gaseous methane is divided by a factor of 0.75. With measurements from a thermocouple and pressure transducer located in the entrance of the methane flow path, the density was obtained and used to calculate the mass flow rate of the

methane. The methane pressure was adjusted to obtain the mass flow rate desired and provide a known tank pressure value prior to testing. The following curve fit equation is used to make conversions from volume (LPM) to mass (kg/s) flow rate when setting the desired flow meter readings and when analyzing the data post-testing:

$$(1) \dot{m} = 0.0017\dot{V}^2 + 0.003\dot{V} - 0.0003$$

A schematic of the propellant delivery system can be observed in Figure 3.9.

Figure 3-10 LN2/GCH4 delivery system configuration

Instrumentation List

- 2 x Omega Cryogenic Pressure Transducer
 - 0-250 psia
 - Used at the injector feed ports to measure inlet pressure to the test article (one for each line)
- 1 x Sensonetics Fast Response Pressure Transducer
 - 0-300 psia
 - Used to record and monitor P_c in the MOAC
- 3 x Omega E-Type Thermocouple
 - 2 installed at both injector feed ports to the test article (one for each line)
 - 1 installed at in the top face of the MOAC to monitor chamber temperature

- 1 x Stellar Differential Pressure Transducer
 - 0-25 psia
 - Used to take the differential pressure across the venturi to calculate LN₂ mass flow rate
- 1 x Omega Flow Meter
 - 0-200 Liters per Minute
 - Used to take the measurement of the volumetric flow rate of the methane into the test article
- 1 x DANTEC Dynamics high-speed camera
 - Used to collect imaging data at a high frequency
- 1 x LED light source
 - Illuminates the background of the MOAC's quartz windows
- 1 x Edmond Optics light diffusing plate
 - Filters the light to provide an adequate background for shadowgraph imaging

3.3.3 Flow Visualization Techniques

The visualization of the liquid core and its breakup mechanisms as it fragments into droplets of ignitable mixture is major product of this study, and several flow visualization techniques were considered and tested to this end. Throughout the project, Schlieren imaging, shadowgraph technique, high speed color recording, and particle image velocimetry were used in some degree or another. A description of each technique and its role in the project follows.

Schlieren Imaging

Schlieren imaging is considered a simple photo-optical technique and these type of systems allow the user to visualize the density variations occurring during fluid interaction of transparent media through light refraction. The installation and operation of a Z-type Schlieren system was part of the early injector characterization efforts at cSETR. The optical system had a traditional configuration and was used to visualize preliminary cold flow runs with liquid nitrogen and candle flames¹⁴. The images obtained were not used for any rigorous liquid core or flame analyses, but served to compliment the project's flow visualization capabilities and provide an expectation for future recordings and optical diagnostics. Some specifications of the optical system's major components are as follows:

Table 3-2 Schlieren system specifications

Component	Type/ Description	Quantity
Camera	Monochrome CCD	1
Light source	Specialty halogen, Oriel 1000 W	1
Mirror	6" diameter, 24" focus length, F no.= 4	2

Figure 3-11 Liquid nitrogen jet visualization with Schlieren Imaging

Shadowgraph Technique

The optical diagnostics hardware used to retrieve shadowgraph imaging data consisted of a specialized National Instruments processor, a high speed DANTEC SpeedSense, S/N: 105 camera, and a timer box. The backlighting of the system was achieved with a light diffusing plate manufactured by Edmond Optics and a pulsing LED source. The program used for data analysis was DANTEC's Dynamic Studio software installed in an adjacent PC.

Figure 3-12 Shadowgraph imaging system layout

The initial installation of the system was done on a work bench inside the Challenger-Columbia Structures and Materials Research Facility at UTEP, and its shakedown testing was performed with deionized water and gaseous nitrogen. The goal of these tests, more than the gathering of scientific data, was to obtain information about the capabilities of the system at hand regarding image quality, the focusing and calibration processes, as well as the synchronization between software and hardware. From these runs, it was understood that the collection of liquid water, or in later tests with condensation from cryogenic flow, in the walls of the MOAC would hinder the visualization of the jets significantly. A sense of the flow rate control required to avoid this was obtained with the pressurization of a water tank, as well as estimates of the time frames needed to obtain a comprehensive observation of the flow. It was determined that after a short time interval (~1-2 seconds) the behavior of the jet was stabilized and due to the high frequencies that the optical equipment was capable of reaching, a large amount of visual data could be obtained in less than one minute. An individual frame taken during the water shakedown tests is shown in Figure 3.12.

Figure 3-13 Cold flow shakedown test with Shadowgraph imaging using deionized water

Once the optical system was integrated and tested it was transferred to an aluminum testing rig inside the Goddard Propulsion Laboratory. After training with a representative from DANTEC several fine tuning sessions, the recording settings were decided to be a collection of 3200 images per run, at a frequency of 200 Hz, over a period of 16 seconds. To arrive at this duration, it had to be ensured that each video would encompass from the beginning of the interaction between the LN_2 and GCH_4 so that it would allow for several instantaneous measurements after recording. Additional specifications (DANTEC Dynamic Studio v3.12 User's Guide) of the shadowgraph system are:

Model: 9070

Max. Resolution: 1280x800 pixels

Bit depth (bits): 8, 12

Frame per second (FPS): 3140/1570

Min. exposure time (μ seconds): 1

Pixel size (microns): 20

Initially, the cold flow tests were expected to produce exclusively qualitative data. It was at the prospect of collecting and comparing jet lengths that a means to ensure accurate measurements was required. The measurement process entailed obtaining a precise scale in the image processing software. More specifically, the clarity of each individual image must be such that the outgoing fluids can be measured in the millimeter scale provided by the software's calibrated database. To do this, a calibration procedure was followed each time a new database (set of individual sessions) was created. The calibration procedure of the image processing software can be found in the Appendix C. Once the database is calibrated and all connections are verified, the test conductors can prepare for a cold flow run. As outlined in the procedure, the interior of the MOAC must be previewed during cooling to ensure proper focus and lighting of the outgoing fluids. The high speed camera must be fixed on the aluminum testing rig on the same plane as the MOAC, the LED source, and the light diffusing plate.

Figure 3-14 Hardware assembly during LN2/GCH4 tests

PIV Testing

PIV testing was incorporated to support the observations and analyses made with the shadowgraph system. In the MOAC, two windows encompass the entire combustion area while the two smaller ones are 3 cm across to allow for a laser sheet to be inserted into the chamber for this very purpose. The targeted flow condition was the same as Case #3 of the revised cold flow test matrix. The propellant properties, test articles, and major hardware components remained unchanged and only the optical diagnostics setup was modified. The same high speed camera and software were used in these experiments, but the camera was placed in a vertical position to accommodate the 90 degree angle with respect to the laser sheet required by the PIV system as seen in Figure 3.15. Additionally, a 520 microns filter was placed in the high speed camera to filter out the ambient light for “noise” cancelling effect. The laser used for these runs was a Dual Power, class 4, Nd: YAG laser with a maximum power output of 400mJ. The pulse duration of the laser firings is set to 4 ns and the unit has a frequency upper limit of 15 Hz.

Figure 3-15 Experimental setup for LN2/GHC4 cold flow tests with PIV

Troubleshooting

One of the major challenges of the project was to ensure the quality of the shadowgraph images. Not only did the images have to support the acquisition of core length data, but allow to clearly visualize the methodology that was followed to analyze the fluid dynamics of each injector. As the project incorporated the DANTEC Dynamics system into the setup, focusing and setting the camera to capture the MOAC's entire area of interest to meet that quality standard posed some difficulties that were overcome with training and feedback from a DANTEC representative. Once the installation and setup was completed and testing began, another challenge was to address the appearance of fogging and freezing of the MOAC's windows. At times, it was possible to mitigate this effect, specially the fogging, by blowing warm air on the outside of the window or waiting a couple hours before the next LN_2/GCH_4 run. However, after more than two cold flow runs, intense freezing could begin to be observed and overusing the warm air posed a risk of damaging the windows.

Figure 3-16 Poor quality LN_2/GCH_4 shadowgraph images displaying freezing (left) and fogging (right)

In the case of the experiments using PIV, the major challenge was an overall lack of signal to the software caused by the fact that the timer box had to be adjusted to read the appropriate PCI card. Finally, although the dual laser mode was activated, only one of the two frames came through in the data acquisition, resulting in barely noticeably breaks in the video.

3.4 Hot Firing Tests

The initial hot fire testing stage is to be a replica of the LN_2/GCH_4 test matrix since there is precedent for the fluids' behavior. These tests are to be conducted in the blast-proof facilities and will involve injecting LOX and GCH₄ into the MOAC and igniting the resulting mixture with cSETR's swirl torch ignition system. The torch igniter will be fed with exclusively gaseous propellants in a mixture ratio range previously tested for reliability. The ignition times must be limited to 2-3 seconds for a total firing time of no more than 10 consecutive seconds. The control of the LOX mass flow rate will be supported with the previous cavitating venturi development performed for the Goddard's propellant delivery system. The upper limit of the mass flow rates will be dictated by the flow measurement instrumentation and adjusted to remain in the MR range of 2-4. The configuration of the delivery lines and the mounting location of the MOAC inside the MASS system are shown in Figure 3.17.

Figure 3-17 Hot firings flow schematic

The recording instrumentation available for these initial tests are a GoPro camera and the high-speed SpeedSense camera used in the cold flow tests. The visual recording instrumentation must be position outside of the MASS optical access window located on its side to avoid damaging the cameras and other accessories. Since the MOAC must be securely fastened to a stainless steel mounting plate resting on the inner rails of the MASS's vacuum chamber, it is necessary to raise the MOAC so that the quartz windows is in the same plane as the vacuum chamber's window and the camera lens. Subsequent testing ought to look into the incorporation of OH luminescence capabilities.

It is recommended that for safety reasons, the testing is conducted without the converging section, exhausting freely onto the ambient until a competent prediction of the chamber pressure's behavior. The alumina silica gaskets placed around the quartz windows should be replaced after each testing session since they show degradation with used may cause leaks or unintended fire hazards. Another preemptive measure is to place ceramic insulators underneath the MOAC TO contain its thermal energy and limit the heat transfer to the mounting surface.

Chapter 4 : Results

4.1 Cold Flow Tests

Thousands of images from over 40 testing and retesting sessions were retrieved with an area of interest from the injector faceplate to the opposite end of the MOAC. Due to the nature of the flow setup and conditions, there were variations between the targeted MR values and the actual calculated values. Pressure, temperature, and image quality were monitored to ensure that the tests reaching the values that were closest to the targets outlined in the test matrix were the ones passed on for analysis. The remaining of this section describes the observations made of the testing environment, the injected fluids, and the obtained core length data.

Propellant Injection

Table 4.1 shows the average fluid properties recorded for the liquid nitrogen during the cold flow tests. This table shows the similarity and repeatability between the inlet conditions observed for liquid nitrogen, which were attempted to be kept constant for the entirety of the cold flow test matrix in each of the test articles.

Table 4-1 LN₂ fluid properties

LN ₂ Average Fluid Properties	Injector A tests	Injector B tests	Injector C tests
Inlet Pressure, MPa	1.51	1.20	1.40
Inlet Temperature, K	111.6	107.4	109.7
ρ_L , kg/m ³	636.7	660.5	631.7
Exit Velocity, m/s	3.6	3.2	3.5
Re	77,592.4	63,536.8	74,714.6
Viscosity, μ Pa-s	59.7	66.9	58.4

Table 4.2 shows the average fluid properties recorded for the gaseous methane during the cold flow tests. The gas, being the fluid varied to achieve the different MR values outlined in the test matrix, was intended to be delivered in the same state throughout testing. The following table compares the true resemblance of the inlet conditions at the annular injection port relevant to the methane's state, while other properties such as delivery pressure, Re, and exit velocity are omitted due to their significant change in magnitude from test to test.

Table 4-2 Average fluid properties recorded for gaseous methane during cold flow testing

GCH ₄ Average Fluid Properties	Injector A tests	Injector B tests	Injector C tests
Inlet Temperature, K	165.9	169.4	168.8
ρ_G , kg/m ³	1.8	1.6	1.5
Viscosity, μ Pa-s	6.4	6.6	6.5

Chamber Pressure Profile

As mentioned above, the chamber pressure was monitored and recorded for several runs and was consistently stable at ~17 psia. The slight pressurization (3-4 psia increase over ambient) observed in the combustion chamber results from the flow buildup in the chamber, which exits through the converging section and is then exhausted onto a venting duct. A pressure profile for both delivery lines and the MOAC is shown in Figure 4.1. The moment where the methane delivery valve is opened to cease the simultaneous flow of liquid nitrogen in both the central and annular orifices can be observed to happen briefly after 3 seconds after the data recording process began in this particular plot. In general, the behavior of the line and chamber pressures was similar to this example in all recordings, in which a higher accumulation of LN2 in

the central injection inlet can be observed, as well as a drop in the annular inlet pressure once the gaseous methane begins to flow after the pre-testing cooling is completed.

Figure 4-1 Typical inlet and chamber pressure profiles for an LN2/GCH4 run

4.1.1 Shadowgraph Technique

Liquid Core Breakup Length Measurements

Throughout the 3200 images recorded per run, a general pattern was observed that consisted on initially observing a clearly defined liquid jet that gradually fell in intensity to a dim and predominantly gaseous flow towards the end of the 16 second run. The significant variation of jet length during this transition would have skewed an average core length measurement if the entirety of the individual images had been considered. Therefore, a time interval showcasing steady flow, meaning that the flow is neither immediate to pre-cooling nor in the process of final vaporization, was located and selected as a pool for individual measurements since this was the period the exhibited the least transient behavior. This steady state interval consisted of approximately 300 images or 1.5 seconds in each run. Ten, evenly spread measurements were

taken using a calibrated measuring scale in DANTEC's Dynamic Studio software. In instances where ligament detachment were observed, the first obvious fragmentation of the liquid core was considered as measuring point. From these measurements, the core breakup length, the parameter directly compared to core length modeling projections and LOX/H₂ breakup profiles, was computed. This parameter is obtained by averaging the jet breakup length measurements and normalizing the result by the central liquid core diameter (2 mm).

The visual measurements obtained from these tests can only be considered an approximation of the true jet length since the intact core may be hidden a dense spray indistinguishable from the liquid. The measuring error was approximated to be $\pm 2\text{mm}$. The image quality in the visual pool of data was deemed sufficient if no fogging or condensation on the windows prevent the measurement of the central liquid core.

Figure 4-2 Cold flow tests' interrogation area and scale

The visual data exhibits subtle but distinguishable differences between the jet lengths and thicknesses produced by the injectors. A color flow distribution of Case #1 for injectors A, B, and C is shown in Figure 4.3 is representative of these differences. The liquid nitrogen core

region behaved similar in the other cases and can be seen in this particular image to be confined to a slender region downstream of the injector faceplate.

Figure 4-3 Color flow distribution for Case #1, from left to right: Injector A, B, and C

The red contour observed in the lower left corner is the LED light source. The breakup point of the core is clarified by the contrasts in the blue scale, where a darker shade signifies a denser liquid mixture. This color scale does not necessarily indicate changes in temperature but denotes the areas of high liquid concentration, consistently lengthier and wider injector B and better defined and slightly shorter with injector C, all when compared with the baseline design of injector A.

Woodward's previous studies in shear coaxial injectors at high momentum flux ratios concluded that higher momentum flux ratios produce shorter core lengths and that large ligaments of liquid form during shear coaxial atomization⁸. The data from this study confirmed these general conclusions. It was logical to expect that higher MR values produced less shearing of the propellants. However, it was found that in the case with the highest MR value, little to no shearing effect was present as evidenced by the comparison with the LN₂ only runs. This suggests that there is an upper limit after which the gaseous fuel is no longer effective in creating the surface instability in which atomization depends. From the shadowgraph imaging results, the recessed post from injector C generates a shorter, denser core in comparison with the other two injector configurations. It was also observed that injector plate geometry for A and C produced

the shortest measure core length values recorded in testing. This means that increasing the magnitude of geometric variable τ_θ has no positive effect in the atomization process, since more spontaneous breakup indicates a more efficient spray production. Still, the effects of the slight variations in breakup length produced by these different test articles are yet to be quantified in combustion conditions. The plots in Figure 4-4 are graphic representations of these observations.

Figure 4-4 Injector core length comparisons with fragmentation models

Each vertical set of data points indicates a case. The measured jet length was determined by evaluating the shadowgraph images during a steady state flow at the specified flow conditions and locating the sharpest transition from a liquid (dark, dense shadow) to gas mixture (light gray shadows). In the cases of large fragments, the measurement was taken at the primary fragmentation or breakup.

The jet breakup length for each injector while running exclusively LN₂ (without any gaseous flow in the annular orifice) was measured to assess the break-up without the methane's shearing effect. The obtained values are hereafter referred to as L₀ and are the following:

Injector A, L₀ = 35.84mm

Injector B, L₀ = 44.21mm

Injector C, L₀ = 42.22mm

These measurements are compared to the breakup lengths observed for the various MR values set in the cold flow tests by calculating a percentage difference, a comparison usually made between two experimental quantities of the same category from which neither is considered objectively correct:

$$\% \text{ Difference} = \left| \frac{\text{First value} - \text{Second value}}{(\text{First value} + \text{Second value})/2} \right| \times 100\%$$

All the other tests (both LN₂ and GCH₄ runs) were subjected to a comparison to the core length models described in section 3.3.1 of this thesis. The percentage difference has also been calculated for the core length measurements and the model projections calculated with the actual experimental conditions retrieved. Table 4.3 contains the jet and breakup length for each run for all three injectors and their comparison with Woodward's and Davis's core length prediction.

Table 4-3 L/D Measurements vs. Models

Injector	Actual MR	Average L (Exper)	L Sample σ_X	L ₀ , L % diff	L/D (Exper)	Woodward L/D	W., Exper L/D % diff	Davis L/D	D., Exper L/D % diff
A	1.5	24.68	2.88	36.88	12.34	8.37	38.40	9.19	29.29
	1.8	24.92	2.46	35.94	12.46	8.72	35.34	9.42	27.82
	3.5	28.08	6.35	24.28	14.04	13.35	5.07	11.62	18.90
	3.6	40.86	2.84	13.09	20.43	13.16	43.26	12.20	50.44
B	2.0	26.23	3.51	51.05	13.12	8.66	40.92	9.59	31.05
	2.9	37.65	3.02	16.03	18.83	9.96	61.59	11.03	52.22
	3.1	48.9	8.24	10.07	24.45	12.09	67.65	11.11	75.03
	3.7	49.99	4.38	12.27	24.99	12.71	65.16	12.24	68.51
C	2.3	24.72	3.82	52.28	12.36	10.97	11.92	9.92	21.90
	2.7	31.97	4.89	27.63	15.98	11.82	29.96	11.19	35.29
	3.7	31.12	6.62	30.27	15.56	12.62	20.83	12.27	23.64
	3.8	39.43	6.17	6.83	19.71	12.58	44.19	12.43	45.32

Core length measurements for Injectors A and C are the ones that most closely resemble the Davis and Woodward fragmentation models, which can be seen to obtain fairly similar approximations. As expected, the higher shearing velocities from the GCH₄ had a more significant effect on the liquid jet break up length. In general, the experimental core length values were consistently greater than the projections for that flow condition. The overall tendencies of the liquid cores seem to follow the mathematical models developed for sprays generated with other propellants in cold flow. From the results, it was concluded that injector B not only produces the longest cores but also deviates the most from the models

A plot including these data points as well as experimental data published by Boniface, Reed, and Woodward et al [10] and the references cited in their study is shown in Figure 4.5.

Figure 4-5 Plot of LOX core length measurements from Boniface, Reeb, Woodward, and this study against gas-to liquid momentum flux ratio

Table 4-4 Non-dimensional Spray Diagnostics Parameters

Injector	Actual MR	V_r	J	We	Oh
A	1.5	203.4	149.2	722,456.7	0.0102

4.1.2 PIV Tests

Three runs replicating Case #3 were completed with the PIV system as the optical diagnostics in place, one for each face plate configuration. Instants of the runs have been captured in Figure 4.6-9 for injectors A, B, and C, respectively, in progressing order with respect to time. In terms of general behavior, the PIV runs confirmed the assessment that, compared to baseline design A, injector B produces a spray that flares more widely thanks to the reduced shearing caused by having a thicker τ_θ . Injector C, once again, produces the shortest spray after having its 5 mm τ_L produce a short mixing period of the propellants prior to injection.

Figure 4-6 PIV Image sequence for Injector A

Figure 4-7 PIV Image sequence for Injector B

Figure 4-8 PIV Image sequence for Injector C

It was determined that all three injectors produce a highly dense liquid that separates into large fragments of liquid, making it difficult for the software to identify and track individual droplets. The droplets were to serve as traceable particles, and for this reason, velocity vector maps were not obtained.

Figure 4-9 Untraceable ligaments observed during PIV testing

The instants that allowed visibility of the greatest amount of individual particles was the end of the runs, when the injection of gas has begun to warm the injector bodies and the liquid begins to vaporize more quickly. Unfortunately, the time window before the mixture begins to exit the injector as invisible gas is too short to obtain reliable velocity data. For this reason, PIV will only be reincorporated as a diagnostic tool for much lower flow rates and future injection hardware iterations.

Chapter 5 : Conclusion

5.1 Summary of Findings

Changes in central post thickness and co-annular orifice recession length with respect to the injection plate do not affect the injection area and for that reason have been largely unaccounted for in parameters traditionally used to describe the spray atomization process. Despite this omission, it was found that τ_θ and τ_L have quantifiable effects in the generated spray flow field. The cold flow experiments using methane supported Woodward's equation and Davis's J correlation for breakup length, which were developed by testing with gaseous hydrogen and nitrogen in cold flow, respectively. This fact suggests that LOX/GCH₄ atomization can be optimized to meet the efficiency levels of hydrogen and other fuels. The observations from the recessed faceplate suggest an improvement in the increase of combustion chamber length available for burning, one of the metrics for assessing atomization efficiency. Lastly, the observed behavior of the propellants supports classical liquid core fragmentation for shear coaxial injection at similar momentum flux ratio values, which has been described as an atomization that results in large liquid structures rather than diffuse droplets.

5.2 Future Work

Although the extent to which other studies' findings, particularly for LOX/H₂, can translate to methane atomization was observed to be within reason, particular ranges of J and other parameters could be narrowed and further studied for specific applications. Furthermore, the cold flow test matrix must be replicated in combustion conditions to study the flame anchoring mechanisms of LOX/CH₄ with cSETR's injection hardware. Lastly, OH luminescence and other applicable optical diagnostics would be valuable in further this combustion

Appendix B

The following is a detailed testing procedure for LN₂/GCH₄ cold flow testing using shadowgraph visualization techniques. Three roles have been assigned: Test conductor A (supervising the LabView data acquisition system), Test conductor B (operating the flow visualization system), and a hardware technician (operating the delivery system instrumentation).

Pretest

1. Hardware technician must inspect the testing rig and surrounding area.
 - a. Check the exhaust path is free from foreign objects and remove any found
 - b. Verify all propellant storage tanks are closed
 - c. Leak check the propellant delivery system with snoop at ~25 psia and fix any leaks found
 - d. Perform a visual inspection to ensure the test article is in place and all instruments and propellant lines are installed correctly
 - e. Put on PPE (Cryogenic handling gloves, apron, and face shield/safety glasses)
2. Test conductor A must complete the following data filing procedure for each session
 - a. Create a folder for the type of testing being performed i.e. “Cold- Geometry B Testing”
 - b. Create a document that lists the inlet conditions for each test planned for that day (desired inlet pressure/temperature) and name it according to the folder created in a i.e. “Cold- Geometry B Testing 12-09-13 Record”
 - c. Leave a section in this document for comments that will contain the following information
 - i. Changes done in the system configuration, i.e. part substitution
 - ii. Renaming of channels if any
 - iii. Troubleshooting procedures that might be useful for subsequent tests
 - iv. A brief identifiable observation of the test, e.g. excessive window fogging

3. Test conductor B must prepare all instrumentation related to the shadowgraph equipment used during the test
 - a. Power ON high-speed camera and light source
 - b. Initiate DANTEC software on the desktop safely installed in the vicinity of the test location
 - c. Preview the visual data feed to ensure that the focus, light, and chamber windows' cleanliness are appropriate (image is clear and covers the entirety of the chamber's inner area).
 - d. End preview and verify that the "record" button is ready to activate the system
4. Test supervisor must now turn ON the power supplies and monitor readings and approve the system's functionality.
 - a. Each valve that will be used must be opened to ensure proper connection. The conductor will specify which valve will be opened and the hardware technician will confirm that it was opened via visual/audio inspection. This process will be repeated for all valves
 - b. Ensure that all pressure transducers and thermocouples are reading ambient conditions (13 +/- 1 psia and 297 +/- 3 K)

Testing Procedure

5. Hardware technician must then set the components to required testing conditions
 - a. Open all tanks that will be used. (1x LN2, 1x GCH4).
 - b. Set LN2 tank to 213 +/-5 psia and GCH4 tank to the pressure specified in the test matrix outlined for the present test.
 - c. Open the manual valve located in the Oxidizer- Fluid bypass to permit cooling
6. Set GCH4 tank pressure according to the desired methane flow rate.
 - a. Open GCH4 tank and fuel line valve
 - b. Observe Omega flow meter reading and communicate to a test conductor.

- c. Regulate GCH4 tank pressure until desired volumetric flow rate appears in the flow meter's reading (see equation (3)).
 - d. Close GCH4 tank and fuel line valve.
- 7. Cool propellant delivery line
 - a. Open LN2 tank valve
 - b. Ensure Needle valve is open to allow LN2 to exit the MOAC freely
 - c. Cease LN2 flow upon observation of the following visual cue: **a visible liquid jet reaches the midpoint of the MOAC's length or beyond.**
 - d. Immediately close the manual valve in the bypass.
- 8. Open LN2 tank and deliver to chill uncooled portions of the LOX line until **a visible liquid jet reaches the midpoint of the MOAC's length or beyond.**
- 9. Immediately begin to shut the Dragon needle valve gradually, until test supervisor A confirms that the MOAC's chamber pressure is indicated to be ~17 psi.
- 10. The methane tank valve is opened to allow its flow to the test article
- 11. Immediately coordinate the simultaneous recording of both visual and measurement data, until the software collects the pre-specified number of frames (see Appendix A)
- 12. Notify the other team members that the propellants' flow and all measurement activities may be stopped at this time.

Post test

- 13. Each run will conclude with an examination of the recently obtained video, which will be played for all team members to decide if the test needs to be repeated.
- 14. If the image evaluation passes its success criteria, close oxidizer/fuel propellant tanks valves
- 15. Hardware technician may re-enter the bunker to shut down the system
 - a. Close all tank valves

- b. Allow system to depressurize by opening all of the valves in the system
(depressurization is defined as all pressure transducers reading 13 +/- 1 psi and all regulators indicating no pressure)
16. Open LN2 tank and begin to purge the delivery system (30 seconds)
17. Close LN2 tank
18. Test supervisors must now store recordings in the folders created in step 2 and rename them to indicate test order i.e. Testing Video 12-09-13 Test 1
19. Turn off all power supplies

Red lines are implemented in our test script to avoid a catastrophic failure of the hardware or facilities. Pressure and temperature redlines will stop the test script in case an overpressure of the system occurs or the temperature of an instrument surpasses its operational range.

Red Lines:

- Line pressure must remain less than 230 psia
- Methane tank pressure must remain less than 230 psia
- Temperature readings must remain between $75K < T < 350K$ for all thermocouples

Appendix C

DANTEC Dynamic Studio Calibration procedure for LN_2/GCH_4 cold flow tests visualization:

1. Power and initiate the DANTEC optical system in Acquisition Mode.
2. Position a ruler inside the MOAC's interrogation area.
3. Supply an additional light source to illuminate the scale of the ruler
4. Preview the image in the PC to ensure the visibility of the scale
5. Acquire and record a sample of visual data
6. Play the sample, and if of satisfactory quality, select the "Save for Calibration" option in the Acquired Data window.
7. A file will automatically be created in the database. Select and right-click on this file.
8. Select the "Measure to Scale" option.
9. A new window will appear. The user is now prompted to select Origin coordinates and two additional points in the image: A and B
10. Click on and drag the placeholder labeled "O" to select an Origin.
11. Click on the A and B placeholders, one at the time and drag to the visible portion of the ruler's millimeter scale.
12. Set a starting and end point in such a manner that the true distance between A and B can confidently be read from the scale, i.e. 30 mm.
13. Save the changes and go back to the Acquisition window.
14. Enable the rulers in the margin of the image and ensure that the dimensions match the known size of the interrogation area.

Curriculum Vitae

Vanessa Dorado was born in El Paso in 1989. She attended school in the neighboring city of Ciudad Juarez, Chihuahua until her high school graduation in 2007. Vanessa then enrolled in El Paso Community College, where she worked as a writing tutor and became a member of the Phi Theta Kappa honor society. In the spring of 2009, she was nominated to be a part of the International Scholar Laureate Program engineering delegation to China and was awarded a Louis Stokes Alliance for Minority Participation summer research assistantship. By the time the summer research academy was over, Vanessa was enrolled full time as a UTEP student in the Mechanical Engineering Department.

As a senior student, she was appointed a research assistant at the Center for Space Exploration Technology Research (cSETR) and moved on to obtain her Bachelor's degree in Mechanical Engineering. Vanessa continued to work at cSETR as a graduate research assistant until the completion of her Master's degree in Mechanical Engineering. As a graduate student, she was awarded a Bridge to the Doctorate Fellowship and completed internship programs at both NASA Marshall Space Flight Center and Los Alamos National Laboratory. Vanessa recently accepted a full-time position with Intergraph Inc. in Huntsville, AL.
