# Acknowledgements

I would like to express my heartfelt gratitude to my doctoral advisor, Dr. Maria C. Mariani, Professor of the Computational Science Program at The University of Texas at El Paso. Her clarity of vision, her expertise in the subject, and her understanding and helpfulness are truly inspiring to me. Aside from introducing me to fascinating ideas and teaching me techniques to make them precise, she has also assisted me to become an independent researcher. Her offer to collaborate on the research of time series analysis has boosted my confidence, and her continuous support during that project has enabled me to thrive.

I also wish to thank the other members of my dissertation committee, namely, Dr. Natasha Sharma, Dr. Thompson Sarkodie Gyan, and Dr. Kristine Garza, faculties of The University of Texas at El Paso. Their generous suggestions, comments, and guidance were invaluable to the completion of this work. I also want to thank Dr. Ming Ying Leung, the Director of Computational Science program for her assistance that enabled me to successfully complete my Ph.D. dissertation.

Last but not least, I am immensely grateful to my family members for their unfailing love and support. I found in my mother, Parul Akter, my intellectual role model whom I idolize. My father Md Abdul Mannan Bhuiyan is always a pioneer to me. I found in my wife, Nusrat Sarmin, a model of love and sacrifice for me. I would also like to express my gratitude to my teachers and friends from my high-school days in Bangladesh to my doctoral years in the City of El Paso, Texas, for their love and trust in me. I admit that, in my growth as a data scientist, the credit goes more to my family, my mentors, and my friends than to myself.

NOTE: This dissertation was submitted to my Supervising Committee on the April, 2020.

# Abstract

This work is devoted to the study of modeling high frequency time series including extreme fluctuations. As the high frequency data are collected at extremely fine scales, the fluctuations can capture the dynamics of data that evolve over time. A class of volatility models with time-varying parameters is used to forecast the volatility in a stationary condition at different lags. The modeling of stationary time series with consistent properties facilitates prediction with much certainty.

A large set of high frequency financial returns, closing prices of stock markets, high magnitudes of seismograms generated by the natural earthquakes, and the mining explosions is studied. The Generalized Autoregressive Conditional Heteroscedasticity (GARCH), Asymmetric Power Autoregressive Conditional Heteroscedasticity (APARCH) and Stochastic Volatility (SV) models are used to predict the data volatility. The data involving statistical noise and inaccuracies are continuously changing over time. Thus a filtering technique is performed to estimate the time-varying parameters by minimizing their variance. It is shown that the stochastic volatility (SV) is a better forecasting tool than GARCH (1, 1) and APARCH models, since it is less conditioned by autoregressive past information. We forecast one-step-ahead log volatility that is able to detect the extreme fluctuations of high frequency data.

A new approach is proposed to simulate the special case of high frequency data that do not fit always with the SV model. As the data reflect stochastic nature of most measurements over time, a stochastic differential equation with Ornstein-Uhlenbeck process has been applied in this case. This analysis helps to achieve the higher accuracy and fidelity for estimating the time-varying parameters of data volatility via Maximum Likelihood Estimation.

# Chapter 1

## Introduction

This chapter discusses on the literature review and research problems of this work. Some basic tools and definitions are briefly presented to facilitate the understanding of the methodologies in the application to the high frequency datasets.

### 1.1 Background & Research Problem

The forecasting of time series with estimation of time-varying parameters is very important in modeling the dynamic evolution of data volatility. It is assumed that a model that attracts the attention of investors can potentially be used to predict key variables, for instance, returns, volatility, and volume of stock market. It is to be noted that the development of forecasting methodologies in geophysics helps us to identify the type of source that generates a recorded seismic signal. This type of methodologies is generally applied to various fields, such as finance, geophysics, and safety of power system [1]. A reliable technique of forecasting, including the related time information, is essential to construct less risky portfolios or to make higher profits without the loss of generality and computational cost.

Financial time series manifests typical non-linear characteristics, and they involve volatility clustering where the returns indicate their dynamism. In this study, we develop a volatility forecasting method in which the logarithm of the conditional volatility follows an autoregressive time series model. R. F. Engle's paper introduced the Autoregressive Conditional Heteroskedasticity (ARCH) model to express the conditional variance of available returns as a function of previous observations [2]. Few years later, S. Bollerslev modi-

fied this concept and generalized the ARCH (GARCH) model that allows the conditional variance to depend on the previous conditional variance as well as on the squares of previous returns [3]. In other words, the system volatility in GARCH model is driven by the observed values in a pre-deterministic fashion. In fact, over the past few decades, a considerable amount of deterministic models has been suggested to forecast the observations, noise, and data volatility [4], [5], [6]. The reason is that they are simple and help to account for clustered errors and non-linearity issues. In the present study, we propose GARCH (1, 1) and asymmetric power ARCH (APARCH) models in a stationary way that is useful in the analysis of high frequency financial time series.

It is now widely believed that the measurements of a sequence of geophysics and finance are stochastically dependent on the time needed. In other words, there is a correlation among the numbers of data points at successive time intervals. In Ref. [7], [8], and [9], the authors used stochastic models to describe a unique type of measurement dependence in geophysical and financial data. It has been observed that the high frequency data may follow different behaviors over time, for instance, the mean reversion or extreme fluctuations. Such observations are unlike those of the classical modeling foundations. But the concept of time-dependent observations suggests that the current information needs to be evaluated on the basis of its past behavior [10]. This behavior of time series makes it possible to effectively forecast volatility and to obtain some stylized facts, namely, time-varying volatility, persistence, and clustering.

A distinctive feature of the high frequency time series is that the deterministic model and other volatility models do not show for a full statistical description of volatility [11]. When there are extreme fluctuations in the time series, the GARCH (1, 1) model predicts the volatility arbitrarily since it cannot capture the high volatile nature of the data [8]. It is because the volatility is not directly observable from the data. If the volatility is low at any data point, it does not imply that the risk of seismic events or financial markets is low too. The reason is that the volatility can be low while the probability distributions of data contain fat tails. So a dataset with low volatility can have much more extreme outcomes

compared to another dataset with higher volatility [12]. In this work, a stochastic model with filtering technique is proposed as a way to estimate the time-varying parameters for data volatility. A continuous-time stationary sequences corresponding to financial returns, seismograms of natural earthquakes, and mining explosions are studied to forecast the stochastic volatility by using estimated parameters. These stationary sequences are very effective to capture the characteristic of time-varying parameters in an appropriate way [13]. The adequacy and stationarity of the data are determined by computing the estimated standard error and some powerful tests respectively, which will be discussed in chapter 3. The main difficulty of SV model is to fit it into the high frequency data with higher accuracy. The reason is that their likelihood estimations involve numerical integration over higher dimensional intractable integrals [14], whose maximization is rather complex. In this case, a recursive filtering technique with initial parameters has been used to estimate the time varying parameters via Maximum Likelihood Estimation (MLE).

Another difficulty of high frequency data is that it contains noisy observations like the values of zeroes for financial returns and seismograms of geophysical time series. The high frequency data follows log-normal distribution that allow us to use log-squared observations to forecast the volatility. However, the high frequency data does not always fit into SV methodology due to the log-squared observations and convergence of MLE is not always guaranteed [7]. In order to solve this problem, a new approach has been developed to simulate the data and then forecast the stochastic volatility, which are discussed in chapter 4. The data aspects and their related properties are now briefly discussed to understand the methodologies when they are fit to the datasets.

### **1.1.1 High Frequency Data and Volatility**

High Frequency data is measured at extremely fine scales like monthly, weekly, daily, hourly, minutely, and second (then divide seconds into fractions) [15]. As the frequency of data appears very quickly, so the movement of such time series cover specific reasons for the fluctuations. Most of the times, the changes in time series variables with high frequency

observations behave very differently than the normal time series fluctuations. For example, the stock prices which are today recorded at seconds or less frequency and investors are creating tools which determine the prediction of next movement and flow of such data to decide whether to invest in stock  $A$  vs. Stock  $B$  in Market  $X$  vs. Market  $Y$ .

The volatility of high frequency data shows how much observations move with a condition. The conditional volatility measure the uncertainty about a variable given model and the information. The volatility of high frequency data changes dramatically at a short interval and the periods of high volatility are sometimes correlated. This establishes that the volatility itself is very volatile. The fluctuations of data typically exhibit the volatility clustering [12]. That is to say, small changes in the price tend to be followed by small changes, and large changes by large ones. The volatility clustering suggests that the current information is highly correlated with past information at different levels.

## 1.2 Stochastic & Deterministic Modeling

Stochastic modeling is an interesting and challenging area of probability and statistics. Let us consider the daily closing prices of stock exchanges as a sequence of random variables,  $S_1, S_2, S_3, \dots$ , where the random variable  $S_1$  denotes the value taken by the series at the first time point, the variable  $S_2$  denotes the value for the second time point,  $S_3$  denotes the value for the third time point, and so on. In general, a collection of random variables,  $S_t$ , indexed by  $t$  is known as a stochastic process. This process describes the characteristics of the data that seemingly fluctuates in a random fashion over time [16].

Stochastic models can be contrasted with deterministic models. A deterministic model is specified by a set of equations that describe exactly how the system will evolve over time [17]. In a stochastic model, the evolution is at least partially random and if the process is run several times, it will not give identical results. Different runs of a stochastic process are often called realizations of the process.

Deterministic models are generally easier to analyze than stochastic models. However,

in many cases, stochastic models are more realistic, particularly for problems that involve small observations at different time level. For example, suppose we are trying to model the management of a rare species, looking at how different strategies affect the survival of the species. In this case, the deterministic models will not hold good as the prediction will show either “definitely extinct” or “definitely survives”. In a stochastic model, there will be a probability of extinction that studies how this is affected by management practices.

### 1.2.1 White Noise

A time series  $\epsilon_t$  is called a white noise, if  $\epsilon_t$  is a sequence of independent and identically distributed (i.i.d) random variables with a mean of zero, finite variance, and no serial correlation [18]. In other words, it has the following properties:

1. Zero mean:  $E(\epsilon_t) = E(\epsilon_{t-1}) = 0$
2. Constant variance:  $E(\epsilon_t^2) = E(\epsilon_{t-1}^2) = \sigma^2 = Var(\epsilon_t)$
3. Uncorrelated in time:  $E(\epsilon_t \epsilon_{t-i}) = E(\epsilon_{t-j} \epsilon_{t-i-j}) = \dots = 0 = Cov(\epsilon_{t-j} \epsilon_{t-i-j}), \forall i \neq j$ .

Here, the property 2 is called as Conditional Homoscedasticity. In particular, if the white noise follows a Normal distribution then it is known as Normal or Gaussian white noise.

### 1.2.2 Autoregressive (AR) Models

A time series is a sequence of measurements of the same variable(s) made over time. In other words, in an autoregressive model, a time series is regressed on previous values of the same time series [19]. For example, if the value of  $y_t$  depends on the value of  $y_{t-1}$ , the AR(1) model is defined as:

$$y_t = \beta_0 + \beta_1 y_{t-1} + \epsilon_t \tag{1.1}$$

where  $\epsilon_t$  is a white noise. In general, the AR( $p$ ) model is defined as:

$$y_t = c + \sum_{i=1}^p \phi_i y_{t-i} + \epsilon_t. \tag{1.2}$$

where  $\phi_1, \phi_2, \dots, \phi_p$  are the parameters of the model and  $c$  is a constant.

### 1.2.3 Autocorrelation

The coefficient of correlation between two values in a time series is called the autocorrelation function (ACF) [19]. For example, the ACF for a time series  $y_t$  is given by:

$$\text{Corr}(y_t, y_{t-k}).$$

where the value of  $k$  is called a lag or time gap. The lag 1 autocorrelation (*i.e.*,  $k = 1$ ) is the correlation between values that are one time period apart. In general, a lag  $k$  autocorrelation is the correlation between values that are  $k$  time periods apart. In time series analysis, the ACF is a way to measure the linear relationship between an observation at time  $t$  and the observations at previous times. If we assume an AR ( $k$ ) model, then we may wish to only measure the association between  $y_t$  and  $y_{t-k}$  and filter out the linear influence of the random variables that lie in between (*i.e.*,  $y_{t-1}, y_{t-2}, \dots, y_{t-(k-1)}$ ), which requires a transformation on the time series.

### 1.2.4 Long Memory Technique

The long memory technique describes the higher order correlation structure of a time series. If a time series  $y_t$  follows a long-memory process, it implies that there is a persistent temporal dependence between the observations widely separated in time. This technique can also be regarded as a fractionally integrated process, *i.e.*, an intermediate phase between stationary and unit root process [20], [21]. Considering an Auto-regressive Integrated Moving Averages (ARIMA) model, the long memory process may be represented as follows:

$$\nabla^\lambda y_t = (1 - L)^\lambda y_t = \varepsilon_t, \tag{1.3}$$

where  $\lambda$  is a fractional difference parameter,  $\varepsilon_t$  is a white noise with variance  $\sigma_\varepsilon$  and  $L$  is a lag operator. The parameter  $\lambda$  identifies a process as the short memory or the long

memory. When the parameter is less than 0.5, the process is long memory. In this study, the estimated parameter  $\lambda$  showed that the datasets follow long memory approach. For details of the algorithm and estimation, the reader is referred to [22].

### 1.2.5 Filtering Approach

The state space model is defined by a relation between the  $m$ -dimensional observed time series,  $\mathbf{y}_t$ , and the  $n$ -dimensional state vector (possibly unobserved),  $\mathbf{x}_t$  [23]. An observed (space) equation is driven by the stochastic process as follows:

$$y_t = Hx_t + v_t \tag{1.4}$$

where  $H_t$  is a  $m \times n$  observation matrix which is stationary and noiseless connection between the state vector and the measurement vector,  $\mathbf{x}_t$  is a state vector of  $n \times 1$ , and  $v_t$  is a Gaussian error term ( $v_t \sim (0, R)$ ).

The unobservable vector  $\mathbf{x}_t$  is generated from the transition equation which is defined as:

$$x_t = \Phi x_{t-1} + \omega_t, \tag{1.5}$$

where  $\Phi$  is a  $n \times n$  transition matrix and  $\omega_t \sim (0, Q)$ . We assume that the process starts with a Normal vector  $x_0$ . From Eqs. (1.4) and (1.5), the estimation is made for the underlying unobserved data  $\mathbf{x}_t$  from the given data  $Y_m = \{y_1, \dots, y_m\}$ . When  $m = t$ , the process is called filtering. In this study, a recursive filtering technique is analyzed to filter out the unnecessary information (noise) for finding the “best estimate” from noisy data.

### 1.2.6 Kalman Filtering

The kalman filtering procedure is used for parameter estimation of a stochastic model. The kalman filtering is advantageous as it is a recursive optimal estimation tool that cleans up the measurements inaccuracies and projects these measurements onto the state estimate [24], [25]. So, the filter keeps track of the estimated state of the system and the variance or uncertainty of the estimate.

In order to estimate the system's state, an average of multiple measurement is taken into account. At initial stage, it is assumed that the estimate  $\hat{x}_{t,t}$  would be the average of all previous measurements ( $z_t$ ) at time  $t$ :

$$\begin{aligned}
 \hat{x}_{t,t} &= \frac{1}{t}(z_1 + z_2 + \cdots + z_t) \\
 &= \frac{1}{t} \sum_{t=1}^t z_t \\
 &= \frac{1}{t} \left( \left( \sum_{t=1}^{t-1} z_t \right) + z_t \right) \\
 &= \left( \frac{1}{t} \sum_{t=1}^{t-1} z_t \right) + \frac{1}{t} z_t \\
 &= \frac{1}{t} \frac{t-1}{t-1} \sum_{t=1}^{t-1} z_t + \frac{1}{t} z_t \\
 &= \frac{t-1}{t} \frac{1}{t-1} \sum_{t=1}^{t-1} z_t + \frac{1}{t} z_t \\
 &= \frac{t-1}{t} \hat{x}_{t,t-1} + \frac{1}{t} z_t \\
 &= \hat{x}_{t,t-1} - \frac{1}{t} \hat{x}_{t,t-1} + \frac{1}{t} z_t \\
 &= \hat{x}_{t,t-1} + \frac{1}{t} (z_t - \hat{x}_{t,t-1})
 \end{aligned}$$

where  $x_t$  is the true value of the observation;  $z_t$  is the measurement value of observation at time  $t$ ;  $\hat{x}_{t,t}$  is the estimate of  $x$  at time  $t$ ;  $\hat{x}_{t,t-1}$  is the previous estimate of  $x$  that was made at time  $t - 1$ . Thus,

$$\hat{x}_{t,t} = \hat{x}_{t,t-1} + \frac{1}{t} (z_t - \hat{x}_{t,t-1}) \tag{1.6}$$

where  $(z_t - \hat{x}_{t,t-1})$  is a measurement residual (innovation) that contains new information. Now the above equation can be expressed as:

$$\boxed{\text{Estimate of current state}} = \boxed{\text{Predicted value of the current state}} + \boxed{\text{Factor}} * \left( \boxed{\text{Measurement}} - \boxed{\text{Predicted value of the current state}} \right)$$

where the factor,  $\frac{1}{t}$ , is defined as a Kalman Gain in the filtering technique. We denote this Kalman Gain as  $K_t$  that explains how much we want to change our estimate by a given measurement. The subscript  $t$  indicates that the Kalman Gain keeps changing with every iteration based on the uncertainty in estimate and uncertainty in measurement. The equation of Kalman Gain is given as follows:

$$\begin{aligned} \text{Kalman Gain } (K_t) &= \frac{\text{uncertainty in estimate}}{\text{uncertainty in estimate} + \text{uncertainty in measurement}} \\ &= \frac{p_{t,t-1}}{p_{t,t-1} + r_t} \end{aligned}$$

where  $p_{t,t-1}$  is the extrapolated estimate uncertainty,  $r_t$  is the measurement uncertainty. From the above equation, it is clear that the Kalman Gain is a number between 0 and 1 ( $0 \leq K_t \leq 1$ ). Now the Eq. (1.6) can be rewritten as follows:

$$\hat{x}_{t,t} = \hat{x}_{t,t-1} + K_t(z_t - \hat{x}_{t,t-1}) \quad (1.7)$$

$$= (1 - K_t)\hat{x}_{t,t-1} + K_t z_t \quad (1.8)$$

As we can see the Kalman Gain ( $K_t$ ) is the weight that is used for the measurement and  $(1 - K_t)$  is the weight that is used for the estimate. When the uncertainty in the measurement is very large and the uncertainty in the estimate is very small, the Kalman Gain is close to zero. So a big weight is given to the estimate and a small weight to the measurement. On the other side, when the uncertainty in the measurement is very small and the uncertainty in the estimate is very large, the Kalman Gain is close to one. So we give a small weight to the estimate and a big weight to the measurement. If the measurement uncertainty is equal to the estimate uncertainty, then the Kalman gain equals to 0.5. We now present an algorithm of Kalman filtering as follows [26]:

#### 1. STEP 0: Initialization

- Initial System Estimate:  $\hat{x}_{1,0}$
- Initial System Uncertainty:  $p_{1,0}$

## 2. STEP 1: Measurement

- Measurement System Estimate:  $y_t$
- Measurement Uncertainty:  $r_t$

## 3. STEP 2: State Update

- Input:  $z_{1,0}, r_t, \hat{x}_{t,t-1}, p_{t,t-1}$
- Kalman Gain:  $K_t = \frac{p_{t,t-1}}{p_{t,t-1} + r_t}$
- State Update:  $\hat{x}_{t,t} = \hat{x}_{t,t-1} + K_t(z_t - \hat{x}_{t,t-1})$
- Covariance Update:  $p_{t,t} = (1 - K_t)p_{t,t-1}$
- Output:  $\hat{x}_{t,t}, p_{t,t}$

## 4. STEP 3: Prediction

- Dynamic Model (State Space Model):  
$$\hat{x}_{t+1,t} = F\hat{x}_{t,t} + G\hat{u}_{t,t}$$
- Covariance Update:  $p_{t+1,t} = Fp_{t,t}F^T + Q$

where,  $F$  is a state transition matrix of coefficients,  $G$  is a control matrix,  $u$  is an input variable, and  $Q$  is a process noise uncertainty. In the prediction step, we see that the Kalman filter produces estimates of the current state variables, along with their uncertainties. It is assumed that the errors terms of this algorithm are Gaussian. Once the outcome of the next measurement (necessarily involved with some amount of error and random noise) is observed, these estimates are updated using a weighted average.

### 1.2.7 Likelihood Approximation

Let  $\varphi$  denote the parameters of the state space model, which are embedded in the system matrices  $H_t, \Phi, v_t$  and  $\omega_t$ . These parameters are typically unknown, but estimated from the data  $Y = y_1, \dots, y_m$ .

The likelihood  $L(\varphi|Y)$  is a function that assigns a value to each point in the parameter space  $\Delta$  which suggests the likelihood of each value in generating the data [7]. However, the likelihood is proportional to the joint probability distribution of the data as a function of the unknown parameters. The maximum likelihood estimation means the estimation of the value of  $\varphi \in \Delta$  that is most likely to generate the vector of the observed data  $y_t$  [27]. The likelihood can be represented as:

$$\hat{\varphi}_{MLE} = \max_{\varphi \in \Delta} L(\varphi|Y) = \max_{\varphi \in \Delta} L_Y(\varphi) = \max_{\varphi \in \Delta} \prod_{t=1}^m f(y_t|y_{t-1}; \varphi) \quad (1.9)$$

where  $\hat{\varphi}$  is the maximum likelihood estimator of  $\varphi$ . Since the natural logarithm function increases on  $(0, \infty)$ , the maximum value of the likelihood function, if it exists, occurs at the same points as the maximum value of the logarithm of the likelihood function. The log-likelihood function is defined as:

$$\hat{\varphi}_{MLE} = \max_{\varphi \in \Delta} \ln L(\varphi|Y) = \max_{\varphi \in \Delta} \ln L_Y(\varphi) = \max_{\varphi \in \Delta} \sum_{t=1}^m \ln f(y_t|y_{t-1}; \varphi). \quad (1.10)$$

Since this is a highly non-linear and complicated function of the unknown parameters, we first consider the initial state vector  $\mathbf{x}_0$  and develop a set of recursions for the log-likelihood function with its first two derivatives [28]. We then use Newton-Raphson algorithm [29] successively until the negative of the log-likelihood is minimized to obtain the MLE.

# Chapter 2

## Data Background

This chapter focuses on the background of data arising in finance and geophysics. We analyzed the high frequency data that includes some extreme fluctuations. In fact, it is the dynamic behavior of the data that encourages us to apply our methodology in this paper.

### 2.1 High Frequency Data with Extreme Fluctuations

#### 2.1.1 Financial Time Series

A large set of daily closing prices for both developed and emergent stock markets is studied. The emergent market indices are studied from two countries: Brazil (BOVESPA), from 04-27-1993 to 10-22-2001; Thailand (SETI), from 07-02-1997 to 10-25-2001. For developed markets the National Association of Securities Dealers Automated Quotations (NASDAQ) and the Standard and Poor's 500 (S&P 500) stock exchanges from USA are analyzed. A good perspective on the trending direction or risk management of the high frequency returns of stock markets as shown in Fig. 2.1. The financial crisis that occurred is evident in the large spikes in the figure.

We then analyzed two financial crashes data that are useful in analyzing their effects and forecasting their stochastic volatilities. The financial crashes cause huge losses in the stock market. For example, the great recession of 2008 had considerable effects on the U.S. and global economy. The financial market around the world suffered great disruptions in asset and credit companies, massive erosions of wealth and innumerable bankruptcies. The high frequency market data (minute by minute) employed in this study are obtained from

Figure 2.1: The closing prices of daily trading observations from the NASDAQ stock exchange.

the Lehman Brothers collapse and Flash Crash event, which occurred in 2008 and in 2010 respectively. So we analyze the high frequency returns from stock companies that were affected by these events. The companies are as: Citi Bank, Bank of America, ExxonMobil corporation (XOM), Walmart Retail company (WMT), Verizon Communications Inc. (VZ), United Technologies Corporation (UTX), McDonalds corporation (MCD) etc. Now the background of Lehman Brothers collapse and the Flash Crash events financial crashes are briefly discussed [30].

### The Lehman Brothers collapse

Lehman Brothers, one of the biggest financial services firm in the world, was brought down by the collapse of the subprime mortgage market. The company was established by Henry Lehman with a general store that sold utensils, dry goods and groceries to cotton farmers in Montgomery, Alabama. Later, his brothers Emanuel and Mayer joined in the business and shifted it from dealing with commodities to merchant banking in New York. In the beginning, the company did pretty well in both domestic and international market, and it played an important role in the subprime market. It expanded into loan origination, gaining five mortgage lenders between 2003 and 2004, including some specializing in subprime

mortgages.

These mortgages were provided to the borrowers with low credits. In 2003, the company made \$18.2 billion in loans and ranked third in lending. However, due to its significant exposure to the US subprime mortgage and real estate markets, highly-leveraged, risk-taking business strategy supported by limited equity; culture of excessive risk-taking and among others reasons, the company filed for Chapter 11 bankruptcy protection on September 15, 2008. At that time, Lehman Brothers was the fourth largest investment bank in U.S.A and employed over 25,000 people across the globe. But it had \$639 billion in assets and \$619 in debt. So it was the largest victim of the subprime mortgage crisis that made a huge financial crash in the stock market. We refer to [31] and references therein for more details.

Figure 2.2: The high frequency returns sample (generated per minute) of DISCOVER after Lehman Brothers Collapse.

## The Flash Crash

The Flash Crash is an event in electronic securities markets where the sudden withdrawal of stock orders quickly increases price declines. This results in the swift sell-off of securities that can happen over a few minutes, resulting in sudden declines. The Flash Crash event occurred on May 6, 2010, was a trillion-dollar financial crash which lasted for about 36

minutes. The magnitude of the crash was intensified as traders reacted to irregularities in the market, for example, the heavy selling in one or many securities and automatically begin selling large volumes at a very fast pace to avoid losses. During this period, the Dow Jones Industrial Average (DJIA) lost trillions of dollars in the value of stocks and shares.

In a report by Nanex LLC [32], high-frequency traders are said to be largely responsible for flash crashes. The rapid and aggressive sale of the E-mini contracts took out several levels of market depth and caused an explosion of quotes and traders in Exchange traded funds, equities and options with a delay of approximately 20 micro seconds (see [33]). The large amount of quotes strained the system, causing prices to sharply decline.

Figure 2.3: The high frequency returns sample (generated per minute) of INTEL after Flash Crash Event.

## 2.1.2 Geophysical Time Series

This subsection deals with the background of geophysical data including high magnitudes and extreme fluctuations. The data contains information about the date, time, longitude, latitude, the average distance to seismic events, average azimuth and the magnitude of each seismic event in the region. For details of the background, the readers are referred to [13]. In this study, we used four datasets of natural earthquakes (EA1-EA4) and four datasets of mining explosions (EX1-EX4) in order to forecast their volatilities. The dynamic behavior of these data are shown in the following subsection:

## Natural Earthquakes Data

The earthquakes used in this study correspond to a set of aftershocks of the June 26, 2014, magnitude  $M=5.2$  intraplate earthquake. It occurred far from any active tectonic boundary, located between the states of Arizona and New Mexico in the USA. We collected the seismograms containing the seismic waves from two nearby seismic stations: IU.TUC and IU.ANMO, that are located between 150 and 400 km from the seismic events. Fig. 2.4 shows examples of the seismograms recorded by the IU.TUC station from one earthquake.

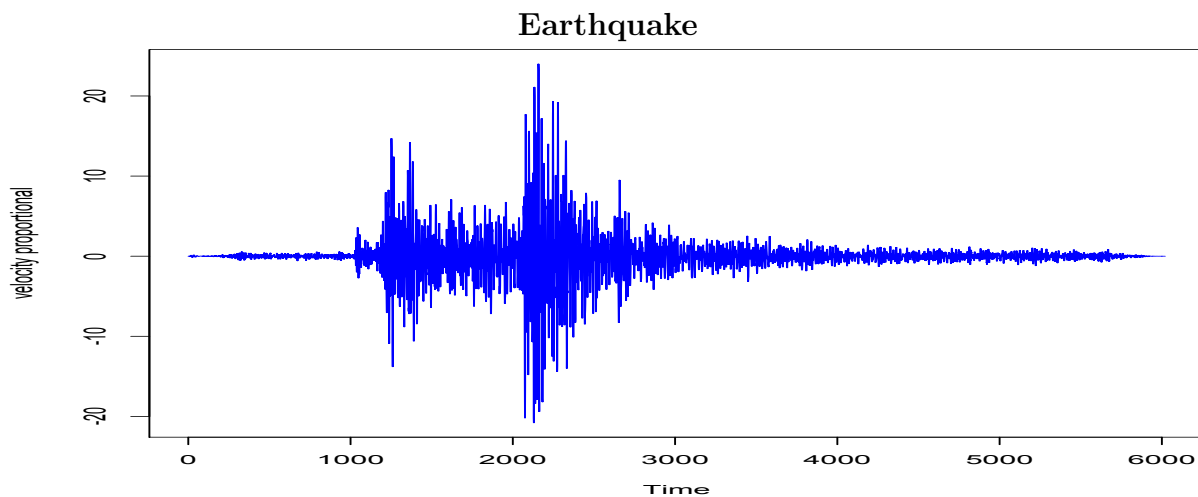

Figure 2.4: The arrival phases from an earthquake as recorded by IU.TUC seismic station.

## Mining Explosions Data

The human made mining explosions cataloged with similar magnitudes as the earthquakes ( $M=3.0-3.3$ ) are studied. These seismic events are located in the same region within a radius of 10 km where a large surface copper mine triggered off several explosions forming part of quarry blasts activities. The broadband seismograms are downloaded from the Incorporated Research Institutions for Seismology Data Management Centers (IRIS DMC). The Seismic Analysis Code (SAC) software was employed to preprocess the data. The displacement of

the ground (in nm) in the vertical (Z-component) direction of sesimograms are used in this analysis. Figure 2.5 shows the arival phases of explosion seismograms recorded by IU.TUC station [34].

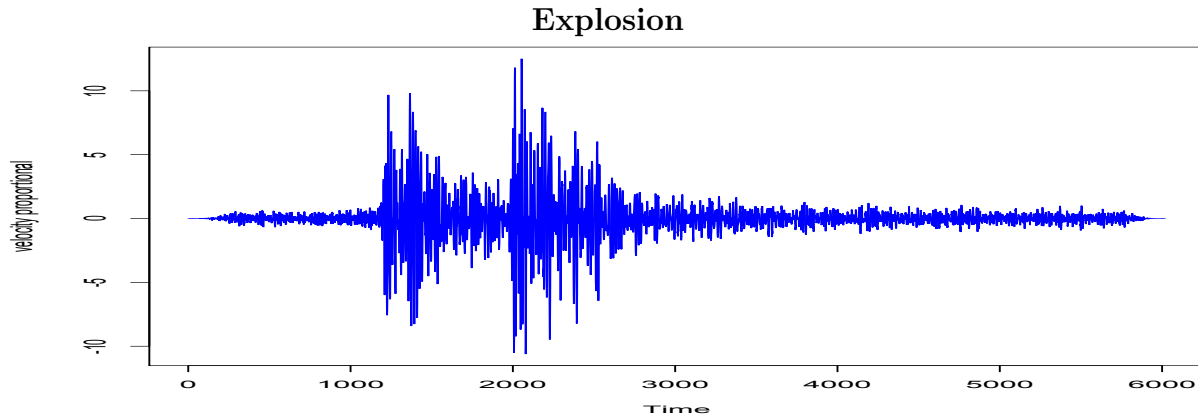

Figure 2.5: The arrival phases from an explosion as recorded by IU.TUC seismic station.

In Fig. 2.4 & 2.5, it is observed that the frequency components change from one interval to another in earthquake or explosion as long as they last. The mean of the series appears to be stable with an average magnitude of approximately zero. This dynamic behavior illustrates the time evolution of the magnitude with its volatility. The volatility changes with time and it is high at a certain intervals, but low at another intervals. The volatility clustering reflects its time varying nature, as well as the mean reversion characteristics of the data.

## 2.2 Stationary Behavior of High Frequency Data

The stationary time series follow some statistical properties that are independent of time. If a time series  $x_t$  is stationary, then its second-order behavior, namely, mean, variance and covariance do not change with time  $t$ . A stationary series is relatively easy to predict and defined as follows:

1.  $E(x_t^2) < \infty$ ,

2.  $E[x(t)] = \mu,$
3.  $\text{Cov } x(s, t) = \text{Cov } x(s + h, t + h), \forall s, t, h \in \mathbb{Z}$

So  $x_t$  must have three features to be a stationary form: finite variation, constant first moment, and the constant variance. In this study, the stationarity of financial, earthquake and mining explosion time series are analyzed by using unit root test. A unit root test provides a way to test whether an autoregressive process is a random walk as opposed to a stationary process. The test-statistics of data are computed by using two unit root tests, namely, the Augmented Dickey Fuller (ADF) [35] and the Kwiatkowski-Phillips-Schmidt-Shin (KPSS) tests [36]. These two tests are powerful and capable of handling complex models.

### 2.2.1 ADF test

The ADF test is an augmented version of the Dicky Fuller test, that is used for large and complicated set of time series models. The ADF test statistic is a negative number. The more negative it is, the stronger the rejection of the hypothesis that there is a unit root at some levels of confidence. It takes into account the basic autoregressive unit root test to accommodate general Autoregressive Moving Average (ARMA)  $(p, q)$  models with unknown orders and non-zero lagged values. The summary statistics of this test are given below when the tests are applied to the high frequency data:

Test interpretation:

$H_0$  : There is a unit root for the time series.

$H_a$  : There is no unit root for the time series, i.e., the series is stationary.

Since the computed p-values in Tables 2.1 and 2.2 are lower than the significance level  $\alpha = 0.05$ , the null hypothesis  $H_0$  is rejected that has a unit root. So the alternative hypothesis  $H_a$  is accepted that the data are stationary time series.

Table 2.1: **ADF t-statistics test for financial data**

Events	Daily data		Minute Data	
	Test statistics	p-value	Test statistics	p-value
Discover	-11.92	0.01	-12.85	0.01
Microsoft	-12.95	0.01	-14.90	0.01
Walmart	-12.87	0.01	-13.56	0.01
JPM Chase	-13.38	0.01	-12.80	0.01

Table 2.2: **ADF t-statistics test for geophysical data**

Events	Test statistics	p-value	Events	Test statistics	p-value
EA1	-42.01	0.01	EX1	-40.30	0.01
EA2	-41.40	0.01	EX2	-36.35	0.01
EA3	-37.39	0.01	EX3	-40.83	0.01
EA4	-39.09	0.01	EX4	-41.94	0.01

### 2.2.2 KPSS test

The KPSS test are used for testing a null hypothesis that an observable time series is stationary against the alternative of no unit root. The major difference between KPSS and ADF tests is that the the KPSS test is able to check stationarity around a deterministic trend. The deterministic trend suggests that the slope of the trend in the series does not change permanently. Therefore, if the series goes through a shock at any time point, the series tends to regain its original path over time. The summary statistics for the results of the KPSS test are displayed in Tables 2.3 and 2.4 respectively.

Test interpretation:

$H_0$  : The series is trend stationary.

$H_a$  : The series is non-stationary

Table 2.3: **KPSS t-statistics test for financial data**

Events	Daily data		Minute Data	
	Test statistics	p-value	Test statistics	p-value
Discover	0.1633	0.1	0.1731	0.1
Microsoft	0.1980	0.1	0.1297	0.1
Walmart	0.1037	0.1	0.0599	0.1
JPM Chase	0.1719	0.1	0.1059	0.1

Table 2.4: **KPSS t-statistics test for geophysical data**

Events	Test statistics	p-value	Events	Test statistics	p-value
EA1	0.0017	0.1	EX1	0.0013	0.1
EA2	0.012	0.1	EX2	0.0014	0.1
EA3	0.0013	0.1	EX3	0.0012	0.1
EA4	0.0012	0.1	EX4	0.0017	0.1

As the computed p-values are greater than the significance level  $\alpha = 0.05$ , the null hypothesis  $H_0$  is accepted for all data sets. Thus the time series used in this paper are stationary time series.

# Chapter 3

## Methodology

### 3.1 Volatility Models

This chapter describes the methodologies that are used to forecast the volatility of high frequency financial and geophysical data. Three types of volatility models and filtering techniques are analyzed to estimate the time-varying parameters of data. It is also shown that how the connection is established between SV model and superposed OU-type models that help to forecast the volatility for special case of high frequency data.

#### 3.1.1 GARCH Volatility Model

The Generalized Autoregressive Conditional Heteroscedasticity (GARCH) model ([2], [3]), was introduced in order to model the fluctuations of the variances of financial data. It is conditional, because the nature of subsequent volatility is conditioned by the information of current period. Heteroscedasticity refers to non-constant volatility. The observations  $y_t$  of high frequency financial time series used in this paper may be represented as:

$$y_t = \sigma_t \eta_t, \quad (3.1)$$

where  $\sigma_t$  is volatility of the observations and  $\{\eta_t\}_{t \in \mathbb{N}}$  is a Gaussian white noise sequence, independent of  $\{\sigma_t\}_{t \in \mathbb{N}}$  and  $\{y_t\}_{t \in \mathbb{N}}$ . This equation can be interpreted as the observation equation of a state space model (see subsection 1.2.5), whereby the state equation is a recursive formula for the state  $\sigma_t$ :

$$\sigma_t^2 = a_0 + a_1 y_{t-1}^2 + b_1 \sigma_{t-1}^2, \quad (3.2)$$

where  $a_0, a_1, b_1 \geq 0$ , so that  $\sigma_t^2 > 0$  for any values of  $y_t$ . Eqs. (3.1) and (3.2) admit a non-Gaussian ARMA (1,1) model [37] for the squared process as:

$$y_t^2 = a_0 + (a_1 + b_1)y_{t-1}^2 + \phi_t - b_1\phi_{t-1}, \quad (3.3)$$

where  $\phi_t = \sigma_t^2(\eta_t^2 - 1)$ . In order to compute the variance at time  $t$ , we follow the standard GARCH ( $m, n$ ) model which is of the form:

$$\sigma_t^2 = a_0 + \sum_{j=1}^m a_j y_{t-j}^2 + \sum_{j=1}^n b_j \sigma_{t-j}^2. \quad (3.4)$$

If  $n = 0$  then the GARCH model changes into an ARCH ( $m$ ) model.

The parameters  $a_0, a_i$  and  $b_j$  are estimated by MLE (subsection 1.2.7) using the likelihood function. Taking into account the Normal probability density function, the conditional likelihood in Eq. (1.10) is obtained from the product of Normal ( $N(0, \sigma_t^2)$ ) densities with  $\sigma_t^2$ . Using the estimated parameters, we obtain one-step-ahead prediction of the volatility ( $\hat{\sigma}_t^2$ ), that is,

$$\hat{\sigma}_t^2 = \hat{a}_0 + \sum_{j=1}^m \hat{a}_j y_{t+1-j}^2 + \sum_{j=1}^n \hat{b}_j \hat{\sigma}_{t+1-j}^2. \quad (3.5)$$

We can analyze the residuals and squared residuals to test the Normality using some statistical tests, for instance, Jarqua-Bera test [38], Shapiro-Wilk test [39], Ljung-Box test [40] and LM-Arch test [41].

### 3.1.2 APARCH Volatility Model

The asymmetric power ARCH (APARCH) model is also used for estimating the data volatility. We see that the above standard GARCH model (Eq. 3.4) estimate volatility ( $\sigma_t$ ) based on the past values of  $y_t^2$ , for example, Eq. (3.4) is a function of  $y_{t-1}^2$ . But the model does not take into account whether the past values of  $y_t$  are positive or negative. It is known that the function of  $y_{t-1}^2$  is symmetric in  $y_{t-1}$ . In this case, APARCH model uses a flexible class of non-negative functions instead of square function. It also offers more flexibility

compared to GARCH model by modeling  $\sigma_t^\delta$ , where  $\delta > 0$  is another parameter. The APARCH  $(p, q)$  model for the conditional standard deviation is as follows:

$$\sigma_t^\delta = \alpha_0 + \sum_{j=1}^p \alpha_j (|y_{t-j}| - \gamma_j y_{t-j})^\delta + \sum_{j=1}^q \beta_j \sigma_{t-j}^\delta \quad (3.6)$$

where  $\delta > 0$  and  $-1 < \gamma_j < 1$ ,  $j = 1, \dots, p$ . Here, if  $\delta = 2$  and  $\gamma_1 = \dots = \gamma_p = 0$ , it will be a form of standard GARCH model.

### 3.1.3 Stochastic Volatility Model

This subsection focuses on the stochastic volatility (SV) model used in this paper. The SV technique implies that the volatility is driven by an innovation sequence, that is, independent of observations [42]. It causes the volatility through an unobservable process that allows it (volatility) to vary stochastically. From Eq. (3.1), the observations  $y_t$  can be expressed as:

$$y_t = \sigma_t \eta_t, \quad (3.7)$$

where  $\sigma_t$  is the data volatility and  $\{\eta_t\}_{t \in \mathbb{N}}$  is a Gaussian white noise sequence.

To develop the SV model, we use the log-squared observations of the time series in Eq.(3.7):

$$\log y_t^2 = \log \sigma_t^2 + \log \eta_t^2$$

which can be rewritten as:

$$m_t = h_t + \log \eta_t^2, \quad (3.8)$$

where  $m_t = \log y_t^2$  and  $h_t = \log \sigma_t^2$ . Thus the observations  $m_t$  are generated by two components namely, the unobserved volatility  $h_t$  and the unobserved noise  $\log \eta_t^2$ . Considering the autoregression, the first term on the right hand side of Eq.(3.8) i.e.  $h_t$  can be expressed as:

$$h_t = \omega_0 + \alpha_1 h_{t-1} + \omega_t, \quad (3.9)$$

where  $\omega_t$  is a white Gaussian noise with the variance  $\sigma_\omega^2$ . Eqs. (3.8) and (3.9) constitute the stochastic volatility model by Taylor [43]. To compute the observation noise, we take

into account the mixtures of two Normal distributions with one centered at zero. Thus we have:

$$y_t = \beta + h_t + \gamma_t, \tag{3.10}$$

where  $\beta$  is the mean of log-squared observations and  $\gamma_t = B_t z_{t0} - (B_t - 1)z_{t1}$ , which fulfills the following conditions:

$$z_{t0} \sim \text{i.i.d N}(0, \sigma_0^2),$$

$$z_{t1} \sim \text{i.i.d N}(\mu_1, \sigma_1^2),$$

$$\text{and } B_t \sim \text{i.i.d Bernoulli } (p),$$

where  $p$  is an unknown mixing probability and i.i.d implies independently and identically distributed. The time-varying probabilities are defined as  $\Pr\{B_t = 0\} = p_0$  and  $\Pr\{B_t = 1\} = p_1$ , where  $p_0 + p_1 = 1$ . The SV model has a characteristic function that describes the probability density function of the model. In particular, the high frequency data in our study seems to have a Normal distribution but not exactly, sometimes there is a little skew on one tail (see the density plot in Figs. 4.4 and 4.5). So, we typically keep the ARCH Normality assumption on  $\epsilon_t$  [2]. In this study, our approach is to estimate the parameters  $\alpha_0, \alpha_1, \sigma_\omega, \sigma_0$  and  $\sigma_1$  and then predict future observations  $y_{n+m}$  from  $n$  observations.

### 3.2 Estimation Procedure

In this subsection, a general estimation procedure for estimating time-varying parameters of SV model are discussed. We will estimate  $x_t$  with its error term:  $e_t = \hat{x}_t - x_t$  and begin the estimation procedure with state space model described in chapter 1, where the assumptions [44] are as:

$$y_t = Hx_t + v_t \tag{3.11}$$

$$x_{t+1} = \Phi x_t + \omega_t \tag{3.12}$$

where  $\Phi_{n \times m}$  is a stationary transition matrix from the state at  $t$  to the state at  $t + 1$ ;  $\omega_t$  is the associated white noise process with known covariance;  $H$  is the noiseless connection

between the state vector and the measurement vector;  $v_t$  is the associated measurement error. The covariances of the two noise terms are assumed as stationary over time and computed as:  $Q = E[\omega_t \omega_t^T]$  and  $R = E[v_t v_t^T]$ . The aim is to find the optimal filter that minimizes the mean squared error,  $E(e_t^2)$ , which is equivalent to  $P_t$  (the error covariance matrix at time  $t$ ):

$$P_t = E[e_t e_t^T] = E[(x_t - \hat{x}_t)(x_t - \hat{x}_t)^T] \quad (3.13)$$

The  $\hat{x}_t'$  is assumed as the prior estimate of  $\hat{x}_t$  which is obtained from the system. Now we can write the state update equation for the new estimate, combining the old estimate with measurement. Eq. (1.7 indicates,

$$\hat{x}_t = \hat{x}_t' + K_t(y_t - H\hat{x}_t') \quad (3.14)$$

where  $K_t$  is the Kalman gain and  $(y_t - H\hat{x}_t')$  is the innovation or measurement residual. We now substitute  $y_t$  from Eq. (3.11) into Eq. (3.14) as:

$$\hat{x}_t = H\hat{x}_t' + K_t(Hx_t + v_t - H\hat{x}_t') \quad (3.15)$$

At this point, we compute the the error-covariance matrix using Eq. (3.13) as:

$$P_t = E[[(I - K_t H)(x_t - \hat{x}_t') - K_t v_t][(I - K_t H)(x_t - \hat{x}_t') - K_t v_t]^T] \quad (3.16)$$

Here,  $x_t - \hat{x}_t'$  is the error of the prior estimate which is uncorrelated with the measurement noise, thus the above equation can be written as:

$$P_t = (I - K_t H)E[(x_t - \hat{x}_t')(x_t - \hat{x}_t')^T](I - K_t H) + K_t E[v_t v_t^T] K_t^T \quad (3.17)$$

$$\Rightarrow P_t = (I - K_t H)P_t'(I - K_t H)^T + K_t R K_t^T \quad (3.18)$$

which is a error-covariance update equation and  $P_t'$  is the prior estimate of  $P_t$ . Now the mean squared error (MSE) can be obtained by computing the trace of following matrix ( $P_t$ ):

$$P_t = \begin{bmatrix} E[e_{t-1} e_{t-1}^T] & E[e_t e_{t-1}^T] & E[e_{t+1} e_{t-1}^T] \\ E[e_{t-1} e_t^T] & E[e_t e_t^T] & E[e_{t+1} e_t^T] \\ E[e_{t-1} e_{t+1}^T] & E[e_t e_{t+1}^T] & E[e_{t+1} e_{t+1}^T] \end{bmatrix} \quad (3.19)$$

So the MSE can be minimized by minimizing the trace of  $P_{tt}$ . The Eq. (3.17) can be furnished as follows:

$$P_t = P'_t - K_t H P'_t - P'_t H^T K_t^T + K_t (H P'_t H^T + R) K_t^T \quad (3.20)$$

The trace of  $P_t$  is given as:

$$\text{tr}([P_t]) = \text{tr}([P'_t]) - 2\text{tr}([K_t H P'_t]) + \text{tr}([K_t (H P'_t H^T + R) K_t^T]) \quad (3.21)$$

To minimize the  $\text{tr}([P_t])$ , we differentiate it with respect to  $K_t$  and set it to zero as:

$$\frac{d\text{tr}[P_t]}{dK_t} = -2(H P'_t)^T + 2K_t (H P'_t H^T + R) = 0 \quad (3.22)$$

Solving for  $K_t$  gives as:

$$K_t = P'_t H^T (H P'_t H^T + R)^{-1} \quad (3.23)$$

which is a Kalman gain equation. The Eq. (3.20) is now updated for the error covariance matrix with this optimal gain. So the updated  $P_t$  is as follows:

$$\begin{aligned} P_t &= P'_t - P'_t H^T (H P'_t H^T + R)^{-1} H P'_t \\ &= P'_t - K_t H P'_t \\ &= (I - K_t H) P'_t \end{aligned} \quad (3.24)$$

which is the update equation for the error-covariance matrix with optimal gain. The three Eqs. (3.15), (3.23) and (3.25) develop an estimate of the variable  $x_t$ . The state projection can be obtained as:

$$\hat{x}'_{t+1} = \phi \hat{x}_t$$

At the same time, we also project the error covariance matrix into the next time interval  $t + 1$  as:

$$e'_{t+1} = x_{t+1} - \hat{x}'_{t+1} = (\phi x_t + \omega_t) - \phi \hat{x}_t = \phi e_t + \omega_t \quad (3.25)$$

So the corresponding error-covariance matrix (using Eq.(3.13)) is computed as:

$$P'_{t+1} = E[e'_{t+1} e'^T_{t+1}] = E[(\phi e_t + \omega_t)(\phi e_t + \omega_t)^T]$$

We know that  $e_t$  and  $\omega_t$  have zero cross-correlation because the noise  $\omega_t$  actually accumulates between  $t$  and  $t + 1$ . So  $P'_{t+1}$  can be written as:

$$P'_{t+1} = \phi P_t \phi^T + Q$$

which shows that it is a recursive filter that gives minimum MSE.

### 3.2.1 Parameter Estimation of SV Model

This subsection describes the estimation of time-varying parameters of SV models. In this case, we used the above filtering technique by three steps namely, forecasting, updating, and parameter estimation [8]. In the first step, we forecast the unobserved state vector  $h_t$  on time series observations as follows:

$$h_{t+1}^t = \alpha_0 + \alpha_1 h_t^{t-1} + \sum_{j=0}^1 p_{tj} K_{tj} \eta_{tj}, \quad (3.26)$$

where the predicted state estimators  $h_t^{t-1} = E(h_t | y_1, \dots, y_{t-1})$ . The corresponding error covariance matrix is defined as:

$$P_{t+1}^t = \alpha_1^2 P_t^{t-1} + \sigma_\omega^2 - \sum_{j=0}^1 p_{tj} K_{tj}^2 \sum_{tj}. \quad (3.27)$$

At this point, the innovation covariances are given as  $\sum_{t0} = P_t^{t-1} + \sigma_0^2$  and  $\sum_{t1} = P_t^{t-1} + \sigma_1^2$ , where  $P_t^{t-1} = \Phi P_{t-1}^{t-1} \Phi^T + V$ ,  $P_0^0 = \sum_0$ ,  $\sum_t = \text{var}(\eta_t)$ , and  $V = \text{var}(w_t)$ . Furthermore, we use Kalman filter to measure the estimates precision, which may be shown as:

$$K_{t0} = \alpha_1 P_t^{t-1} / (P_t^{t-1} + \sigma_0^2) \text{ and } K_{t1} = \alpha_1 P_t^{t-1} / (P_t^{t-1} + \sigma_1^2). \quad (3.28)$$

The second step deals with updating results while we have a new observation of  $y_t$  at time  $t$ . The prediction errors of the likelihood function are computed using the following relations:

$$\eta_{t0} = y_t - \beta - h_t^{t-1} \text{ and } \eta_{t1} = y_t - \beta - h_t^{t-1} - \mu_1. \quad (3.29)$$

For estimating the parameters, we complete the updating step by assessing the time-varying probabilities (for  $t = 1, \dots, m$ ):

$$p_{t1} = \frac{p_1 d_1(t|t-1)}{p_0 d_0(t|t-1) + p_1 d_1(t|t-1)}$$

and  $p_{t0} = 1 - p_{t1}$ ,

where  $d_j(t|t-1)$  is considered to be the conditional density of  $y_t$ , given the previous observations  $y_1, \dots, y_{t-1}$ .

Since the observation noise of this model is not fully Gaussian, it is computationally difficult to obtain the exact values of  $d_j(t|t-1)$ . Hence, we use a good approximation of  $d_j(t|t-1)$  that provides Normal density which is:  $N(h_t^{t-1} + \mu_j, \sum_{t_j})$ , for  $j = 0, 1$  and  $\mu_0 = 0$ .

Finally, we estimate the parameters  $(\Theta = (\alpha_0, \alpha_1, \sigma_w, \beta, \sigma_0, \mu_1, \sigma_1)')$  by maximizing the expected likelihood, where the MLE is represented as:

$$\ln L_Y(\Theta) = \sum_{t=1}^m \ln \left( \sum_{j=0}^1 p_j d_j(t|t-1) \right). \tag{3.30}$$

### 3.3 The Superposed Ornstein-Uhlenbeck Process

This subsection deals with a stochastic differential equation arising from the superposition of independent Ornstein-Uhlenbeck processes driven by a  $\Gamma(a, b)$  process. Superposition of independent  $\Gamma(a, b)$  Ornstein-Uhlenbeck processes offers analytic flexibility and provides a class of continuous time processes capable of exhibiting long memory behavior. The methodology is applied to the high frequency data in order to simulate them [7].

A process is an Ornstein-Uhlenbeck process if it is *cádlág* (i.e. it is right continuous and has a left limit at every point) and satisfies the stochastic differential equation,

$$dS_t = -\lambda S_t dt + dZ_{\lambda t}, S_0 > 0, \quad \lambda \in \mathbb{R}^+. \tag{3.31}$$

where  $S_t$  is a continuous and non-negative stochastic process,  $Z = \{Z_{\lambda t}\}_{t \geq 0}$  is a Lévy

process and the rate parameter  $\lambda$  is a positive number. The process  $Z = \{Z_{\lambda t}\}_{t \geq 0}$  is termed the background driving Lévy process (BDLP).

If we consider the unusual timing in the BDLP, the solution to Equation (3.31) is

$$S_t = e^{-\lambda t} S_0 + \int_0^t e^{-\lambda(t-q)} dZ(\lambda q). \quad (3.32)$$

In order to obtain the analytic flexibility and to ensure correlation structures for the process  $S_t$ , we consider the sum of two independent Ornstein-Uhlenbeck processes in Eq. (3.32), where each component process is an independent Ornstein-Uhlenbeck process with rate parameters  $\lambda_1$  and  $\lambda_2$ :

$$\begin{aligned} S_t = & w_1 S_1 e^{-\lambda_1 t} + \int_0^t w_1 e^{-\lambda_1(t-q)} dZ(\lambda_1 q) \\ & + w_2 S_2 e^{-\lambda_2 t} + \int_0^t w_2 e^{-\lambda_2(t-q)} dZ(\lambda_2 q), \quad t \geq 0. \end{aligned} \quad (3.33)$$

The approach adopted in this work specified a parametric form for the marginal distribution of Eq. (3.33) and then work out the corresponding distribution of BDLP. We will do this by specifying a distribution for the Lévy process and simulate the data via BDLP.

### 3.3.1 Parameter Estimation

A stochastic process  $S = \{S_t, t \geq 0\}$  with parameters  $u$  and  $v$  is a Gamma process if it fulfills the following conditions:

1.  $X_0 = 0$ .
2. The process has independent increments.
3. The process has stationary increments.
4. For  $m < t$ , the random variable  $S_m - S_t$  has  $\Gamma(a(t - m), b)$  distribution.

Recall that a random variable  $S$  has a Gamma distribution  $\Gamma(u, v)$  with rate and shape parameters  $u > 0$  and  $v > 0$  respectively, if its density function is given by:

$$f_S(s; u, v) = \frac{v^u}{\Gamma(u)} s^{u-1} e^{-vs}, \quad \forall s > 0, \quad (3.34)$$

where  $\Gamma$  denotes the Gamma function. The  $\Gamma(a, b)$  process has a Lévy density given by  $u(x) = ax^{-1}e^{-bx}, x \neq 0$ . The  $\Gamma(a, b)$  distribution is known to be self-decomposable. Therefore, taking into account the BDLP,  $Z$  has a Lévy density given by

$$w(x) = uve^{-vx}, x \neq 0$$

and the associated cumulative function is given as:

$$k(m) = \frac{uv}{v+m} \tag{3.35}$$

So it is concluded that the BDLP for the  $\Gamma(a, b)$  process is a compound Poisson process which jumps a finite number of times in every compact time interval. Now a proposition is followed as:

*Suppose that  $\{Z_t\}_{t \geq 0}$  is a Lévy process such that  $E(Z(1)) = \mu < 1$  and  $Var(Z(1)) = \sigma^2 < 1$ . Assume that  $\lambda_1, \lambda_2 > 0$ , then the followings are true:*

1.  $E(X_0) = \mu$
2.  $Var(X_0) = \frac{\sigma^2}{2}$

From this proposition, the parameters  $\mu$  and  $\sigma^2$  can be expressed as related to  $a$  and  $b$ :

$$a = \frac{2\mu^2}{\sigma^2} \text{ and } b = \frac{2\mu}{\sigma^2}$$

Now the intensity parameter  $\lambda_1$  is estimated by taking into account the autocorrelation function of (3.33) i.e.,

$$\rho(k) = w_1e^{-\lambda_1|k|} + w_2e^{-\lambda_2|k|}, \tag{3.36}$$

where  $w_1 + w_2 = 1$  for any  $k \in \mathbb{R}^+$ .

From (3.36),  $\lambda_1$  can be computed by assuming  $\lambda_1 = \lambda_2$  and  $k = 1$ . This results in

$$\lambda_1 = -\log(\hat{\rho}(1)) \tag{3.37}$$

where  $\hat{\rho}(1)$  denotes the empirical autocorrelation function of lag 1 based on the time series data sets. Once  $\lambda_1$  is estimated,  $\lambda_2$  is adjusted to obtain  $\lambda_2$  in order to fit the

superposed  $\Gamma(u, v)$  Ornstein-Uhlenbeck model. Then the data is simulated the based on the parameters  $u, v, \lambda_1, \lambda_2$  that are estimated from the original data. For the details of the methodology, the readers are referred to [8] and references therein.

# Chapter 4

## Results & Discussion

This chapter focuses on the analysis of volatility models and a simulation technique that are applied to the high frequency datasets contained extreme fluctuations. The estimates of time-varying parameters and one-step ahead predicted volatility are presented to detect the extreme fluctuations. The analyses were performed by R and Python programs.

### 4.1 Analysis of Volatility models

This section deals with the results of volatility models that are applied to the daily returns of financial market data, emergent market data, developed market data, minute by minute returns data, and some geophysical data. In chapter 2, Figs. 2.2-2.5 provide a good perspective on the trending direction or risk management of the high frequency returns of stock markets or extreme fluctuations of seismic events. The extreme fluctuations that occurred is evident in the large spikes in the figures. We see that the volatility of data changes dramatically at a short interval and that the periods of high volatility are sometimes correlated. This establishes that the volatility itself is very volatile. The fluctuations of stock returns or seismic events typically exhibit the volatility clustering that suggests that the current information is highly correlated with past information at different levels.

#### 4.1.1 Results of GARCH Model

The GARCH volatility model is used to predict the volatility of high frequency financial market returns in U.S.A. such as the Citi Bank, the Microsoft company, the Bank of America, the Discover Financial Services, the INTEL semiconductor manufacturing company,

the IBM hardware company, the Walmart retail company, the IAG stock exchanges stock markets and among others. In this dissertation, the estimated parameters, standard errors, and forecasting behaviors of two stock companies: Citi Bank and Microsoft stock exchanges are presented (see Tables 4.1-4.4 and Figs. 4.1-4.2). The results of other stock markets data can be found in [22].

The estimates of the parameters  $a_0$ ,  $a_1$ , and  $b_1$  of the GARCH (1, 1) model are stable, as the GARCH-statistic shows (see Tables 4.1-4.4). Also, the estimated standard errors of the parameters in most cases are small. The smaller p-values ( $<$  significance level) provide strong evidence that the GARCH (1, 1) model with the specified parameters is a good fit for our data. The volatility level of persistence can be determined by non-negative parameters  $a_1$  and  $b_1$  from these tables. It is observed that the constraint  $(a_1 + b_1)$  is less than 1, which allows for the existence of a stationary solution. This also supports the results of stationary tests in subsection 2.2.

The standardized residuals (R) tests for the Citi Bank and the Microsoft stock exchanges are summarized in Tables 4.3-4.4. The Jarque-Bera and Shapiro-Wilk tests of Normality strongly reject the null hypothesis that the white noise innovation process  $\eta_t$  is Gaussian. The p-values ( $> 0.05$ ) of Ljung-Box test for squared residuals (at lag 10, 15, 20) and LM-Arch test suggest that the model fits the data well, with the exception of the non-normality of  $\eta_t$ . It is because the null hypothesis cannot be rejected at any reasonable level of significance.

To facilitate the understanding of forecasting concepts, we superimpose the plot of one-step-ahead predicted volatility with high frequency stock market data in Figs. 4.1-4.2. The predicted log volatility is displayed as grey color across the original time series (blue color). It visually shows how the values of predicted volatility differ over time and able to detect the extreme fluctuations.

## Limitations

There are some limitations of GARCH (1,1) model itself in the application to the high frequency financial datasets. It is evident that the positive and negative high frequency returns have the same effect, because volatility depends on squared returns. The model does not help to understand the source of variations of a financial time series. That is to say, the cause of the variation in volatility is unknown. The model provides only a mechanical way to describe the behavior of conditional variance. The grey lines during financial crashes (in Figs. 4.1-4.2) indicate that the model tends to over predict the volatility, because it is often restrictive due to the tight constraints on parameters ( $\alpha_0, \alpha_1, \beta_1 \geq 0$ ).

### 4.1.2 Results of APARCH Model

In this subsection, the results of APARCH model are discussed, which can solve a limitation of GARCH model. The leverage effects states that the large negative returns of high frequency data appear to increase volatility compared to positive returns of the same magnitude. The reason is that the GARCH model estimates the volatility as a function of squared past values, so the positive or negative returns have the same effect. We avoid this issue by using APARCH model that replaces the square function with a flexible class of non-negative functions. The estimation of time varying parameters and one-step-ahead predicted volatility for Microsoft stock market is summarized in Table 4.5. We see that the estimate of  $\delta$  is 1.360 with a standard error of 0.488, so there is strong evidence that  $\delta$  is not 2, which confirms the APARCH condition (see subsection 3.1.2). Also,  $\hat{\gamma}_1$  is  $-0.99$  with a standard error of 0.109 and p-values of  $2E-16$ , so we reject the null hypothesis that  $\hat{\gamma}_1 = 0$ , and conclude that there is a statistically significant leverage effect in the process. Fig. 4.3 shows the original high frequency returns (blue color) and corresponding predicted log-volatility (grey color), where we conclude that the APARCH volatility has higher ability to detect the extreme fluctuations compared to GARCH volatility.

Table 4.5: **APARCH statistics for the Microsoft stock exchange**

### 4.1.3 Results of Stochastic Volatility Model

This subsection deals with the stochastic nature of high frequency data including extreme fluctuations. The stochastic volatility model is analyzed on the Lehman Brothers collapse data, Flash Crash events data, natural earthquakes, and mining explosions data. The GARCH and APARCH models differ from the SV model in the sense that, unlike the SV model, they do not have any stochastic noise. The SV model is characterized by the fact that it invariably contains its probability density function. The histograms of natural earthquakes and mining explosions data are presented in Fig. 4.4. The maximum likelihood is computed by taking into consideration the conditional Normal distribution of the datasets.

For the datasets described in this paper, the ARCH Normality assumption is kept on volatility  $\eta_t$ . Therefore, the  $\log\eta_t^2$  is distributed as the logarithm of a chi-squared random variable with one degree of freedom whose mean is -1.27 and variance is 4.93. In Fig. 4.5 (a, b), we see a clear representation of the density of  $\log(\chi_1^2)$  and fitted Normal mixture of financial time series. It is obvious that the density of financial time series is skewed with a long tail on the left.

(b) The Bank of America

Figure 4.5: Density plot of  $\log(\chi_1^2)$  (solid curves) and the fitted Normal mixture distribution (dashed red curves) from (a) the JPMorgan Chase and (b) the Bank of America stock exchanges.

The parameters from time-varying Eqs. (3.9) and (3.10) were initialized in order to observe the performance of the SV algorithms for each dataset described above. We set the initial values to be  $\alpha_0 = 0, \alpha_1 = 0.95, \sigma_\omega = 0.5, \sigma_0 = 1, \mu_1 = -3, \sigma_1 = 2$  and  $\beta$  (the mean of the observations). In order to maximize the Eq. (3.30), the innovation processes for Eqs. (3.9) and (3.10) were fitted to the data by taking into consideration this time-varying probability ( $p_1 = 0.5$ ).

Tables 4.6-4.9 summarize the estimation of parameters ( $\alpha_0, \alpha_1, \sigma_\omega, \beta, \sigma_0, \mu_1$  and  $\sigma_1$ ). The estimated error in these tables makes two things evident: firstly, the estimates are close to the true parameters; secondly, the algorithm of the SV model aligns with the financial and the geophysical data. The variance  $\sigma_w^2$  of the log-volatility process measures the uncertainty about the future volatility of data. If the value of  $\sigma_w^2$  is zero, it is not possible to identify the SV model. The parameter  $\alpha_1$  is considered as a measure of the persistence of shocks to the volatility. Tables 4.6-4.9 indicate that  $\alpha_1$  is less than 1, which suggests that the latent volatility process and  $y_t$  are stationary. This confirms the results of section 2.2.

In these tables, we also notice that  $\alpha_1$  is near to unity and  $\sigma_w^2$  is different from 0, which means that the evolution of volatility is not smooth over time. This also suggests that the time series used in this paper could be heteroscedastic by nature, that is, there is a non-constant conditional volatility over time. So, it is very useful to control the risk or to mitigate the effect of hazards. Figs. 4.6-4.9 show forecasting behaviors of two stock companies, one natural earthquake dataset and one mining explosion dataset. The original high frequency data (blue color) are shown with corresponding log-predicted volatility (red color) in these figures. It is clear the stochastic volatility is able to detect the financial crashes or extreme fluctuations for both financial and geophysical data. For the results of other datasets, the reader is referred to [34] and [22].

## 4.2 A new approach for fitting SV model

This subsection deals with a new approach for fitting SV model, when the high frequency data contain noisy observations. The stochastic volatility (SV) model described in section 4 is used to estimate the volatility of a log-squared observations via MLE. However, we observed that the financial data does not always fit into SV methodology and so convergence of MLE is not always guaranteed. It is because the high frequency data contain some unusual observations and zero returns as well. Thus, the stochastic volatility model is not always applicable to forecast data volatility. To avoid this problem, the model described in section 3.3 is employed to simulate the data based on their dynamic behavior.

We first used the superposed Ornstein-Uhlenbeck model with the Lévy driven process. The BDLP for the superposed  $\Gamma(u, v)$  Ornstein-Uhlenbeck model has been shown to be a compound Poisson process ([7]). The data is simulated using the solution of the stochastic differential equation via the BDLP. A Matlab program was developed to simulate the process using different time steps. Table 4.10 summarizes the estimation of parameters  $\lambda_1, \lambda_2, w_1, w_2$  for NASDAQ, S&P 500, BVSP and SETI stock exchanges when the superposed  $\Gamma(u, v)$  Ornstein-Uhlenbeck model was applied to the data. We obtained  $\lambda_2$  by adjusting  $\lambda_1$  in order to fit the superposed  $\Gamma(u, v)$  Ornstein-Uhlenbeck model.

Table 4.10: Simulation results for the developed and emergent market indices.

Stock Exchange	$\lambda_1$	$\lambda_2$	$w_1$	$w_2$	RMSE
NASDAQ	0.003	8	0.47	0.53	1.34
S&P 500	3.2E-04	32	0.30	0.70	1.99
BVSP	0.0017	12	0.20	0.80	1.66
SETI	0.0074	38	0.30	0.70	0.32

The simulated data mimics the original financial time series data. This is observed from the estimates and RMSE in Table 4.10. Also, the simulated data exhibits long memory behavior which facilitate prediction using the SV model. In order to fit the SV model, the

distribution of errors of the data are analyzed (Fig. 4.10). The following figures show that the error terms follow almost normal distributions. So the ARCH Normality condition is assumed on the basis of volatility  $\eta_t$  described in Eq. (3.1).

Figure 4.10: Density plot of the fitted Normal mixture distribution from (a) NASDAQ and (b) BVSP stock exchanges.

The above figures show that the density of financial time series is skewed with a little tail on the left. Table 4.11 and Figs. 4.11 - 4.12 summarize the estimation of parameters ( $\alpha_0, \alpha_1, \sigma_w, \lambda, \sigma_0, \phi_1$  and  $\sigma_1$ ) and predicted volatility with  $\pm 2$  errors for NASDAQ and BVSP stock market data. For the results of other stock market datasets, we refer the reader to [22]. The advantage of this methodology is that the estimates obtained are stable around the true value and also the low errors indicate that the estimation procedure is accurate, therefore producing a higher forecasting accuracy. Thus, our estimation algorithm is feasible with large data sets and have good convergence properties.

Table 4.11: Summary statistics for the developed and emergent market indices.

Parameter	S&P 500	Standard Error	BVSP	Standard Error
$\alpha_0$	9.53E-02	0.07950	8.906E-02	0.0227
$\alpha_1$	9.79E-01	0.00870	9.807E-01	0.0029

# Chapter 5

## Other Researches

This chapter deals with our other researches on different types of data. The machine learning (ML) techniques (supervised and unsupervised), Dynamic Fourier models, wavelet models are studied on public health (e.g., breast cancer data, heart disease data, diabetes data, autism spectrum disorder data), financial and geophysical time series. In this chapter, we briefly discuss on the machine learning techniques when they are applied to the diabetes and heart disease datasets. The readers are referred to [13], [30], [45] and [46] for the details of data backgrounds, machine learning algorithms, Dynamic Fourier techniques, wavelet models and the results of other datasets.

### 5.1 Machine Learning Algorithms

Machine learning (ML) techniques help to detect and classify chronological diseases like cancer, heart disease, tumor, diabetes and so on. These techniques are useful to many statistical, probabilistic, and optimization processes that allow computers to consider past observations and to detect the pattern of the disease. Researchers have recently attempted to use ML techniques (especially the supervised and unsupervised ones) in this case. The reason is that the techniques help us to identify the sources and to order the variables in terms of importance in causing chronological disease.

In this study, we first did the exploratory analysis to see the association, correlation and frequency distribution of the features, which are very effective in capturing the characteristic and patterns of data correctly. Then the data is randomly split into training set (67% for building a predictive model) and test set (33% for evaluating the model). The prediction

mean squared error (PMSE), miss-classification rate (MCR), and prediction accuracy using the Receiver Operating Characteristic (ROC) curve are computed in order to validate the fitted model with data. The analyses were performed by Python programs.

### 5.1.1 Analysis of Fitted models

The machine learning models are trained with data to accurately predict whether an individual has been diagnosed with disease (breast cancer, heart disease, diabetes or Autism spectrum disorder). The models used in this research are as: Logistic regression, Ridge regression, Principal component regression, Random Forest and Support vector machine. However, the problem of machine learning techniques is to fit them into the data due to over-fitting, under-fitting, and bias-variance issues. In this case, the regularization technique and cross-validation are used to estimate the tuning parameters of each model corresponding to the low mean squared error. The adequacy and predictive ability of the data are determined by computing sensitivity, specificity, accuracy and confidence interval. Now the results of five ML algorithms are briefly presented when they are applied to diabetes and heart disease datasets.

#### Results of Logistic regression

The logistic regression technique have been used for train data to build a predictive model. In this case, the lasso regularization ( $L_1$  norm) is employed to obtain the tuning parameter  $\lambda$  via cross-validation. The  $L_1$  penalty is used for both variable selection and shrinkage, since it has the effect of forcing some of the coefficient estimates to be zero. Table 5.1 represents important predictors using the best predictive model with  $L_1$  penalty. It is clear that *number of times pregnant (preg)*, *plasma glucose concentration (plas)*, *body mass index (mass)*, *diabetes pedigree function (pedi)*, and *age* are important predictors for identifying a diabetes patient and *exercise induced angina (Exang)*, *number of major vessel (Ca)*, *the slope of the peak exercise ST segment (Slope)*, *thalassamia (Thal)* , *chest pain (Cp)*, and

*ST depression induced by exercise relative to rest (oldpeak)* are important predictors for identifying a heart disease patient. The test data is predicted using this predictive model and evaluated the model using different metrics.

Variables	Coefficients
preg	0.0323
plas	0.0250
pres	0
skin	0
insu	0
mass	0.0407
pedi	0.2950
age	0.0121

Table 5.1: Coefficients of important predictors using LGR ( $L_1$ ) model for Diabetes data.

### Results of Ridge regression

The Logistic regression model with  $L_2$  penalty term (Ridge regression) is also studied on the datasets. An advantage of  $L_2$  penalty is that it overcomes the multicollinearity issue of the datasets. It has more power to reduce the over-fitting issue of data compared to  $L_1$  regularization. The parameter  $\lambda$  is tuned (optimized) until we find a model that fits well to the train data. In this case, the tuning parameter is selected by 10-fold cross validation procedure. From Table 5.3, it is clear that the prediction mean squared error and miss-classification rate of this model are very low for both diabetes and heart disease data.

Table 5.2: Coefficients of important predictors using LGR( $L_1$ ) model for heart Disease data

## Results of Principal Component Regression

A dimension reduction tool, namely principal component regression (PCR) is studied to reduce the set of predictors of datasets. An advantage of principal component analysis is that it transforms the high dimensional correlated data into uncorrelated data with same amount of variation. In this case, the entire dataset is transformed into three principal components to build the predictive model. The first principal component contains most of the variability in the data. PCR also overcomes the multicollinearity issue of the datasets used in this study. We obtained a very good prediction accuracy on test data, which are 88.17% for heart disease data. The predictive performance of PCR compared to the other methodologies are shown in Table 5.3.

## Results of Random Forest

The Random forest model is fitted into train data with optimized number of trees. For the heart disease dataset, the tuning parameters are 500 trees and 3 sampled variables at each split. We obtained a very good prediction accuracy on test data, which are 74.80% for diabetes disease. An important feature of random forest is that we made an order of the predictors in terms of importance using Mean Decrease Accuracy and Mean Decrease Gini indices [45]. From Fig. 5.1, it is clear that the plasma-glucose-concentration (*plas*) is the most important variable and triceps-skin-fold-thickness (*skin*) is the least important variable in causing diabetes.

## Results of Support Vector Machine

Last, a support vector machine (SVM kernel) technique is studied to classify the disease datasets. The reason of using SVM kernel function is that it maps the non-linear separable dataset into a higher dimensional space where a hyperplane is able to separate the classes (target variable) linearly. To fit the model, the dataset is first standardized and trained with 10-fold cross-validation procedure. The model is evaluated with different cost levels

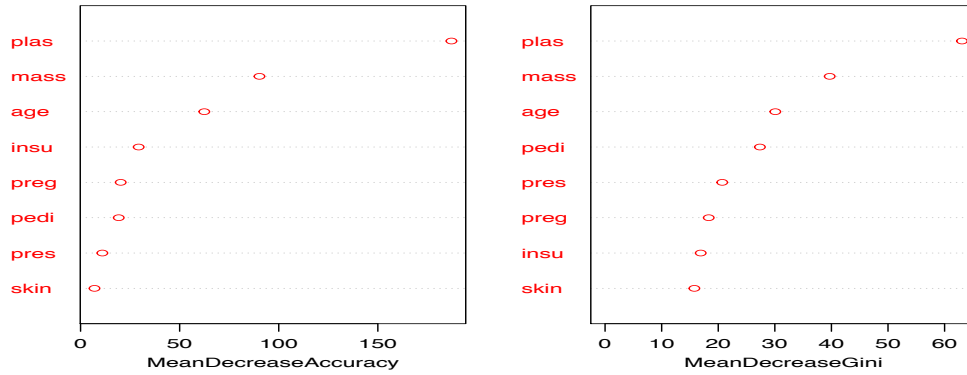

Figure 5.1: Variable importance plot using Random Forest model for Diabetes data.

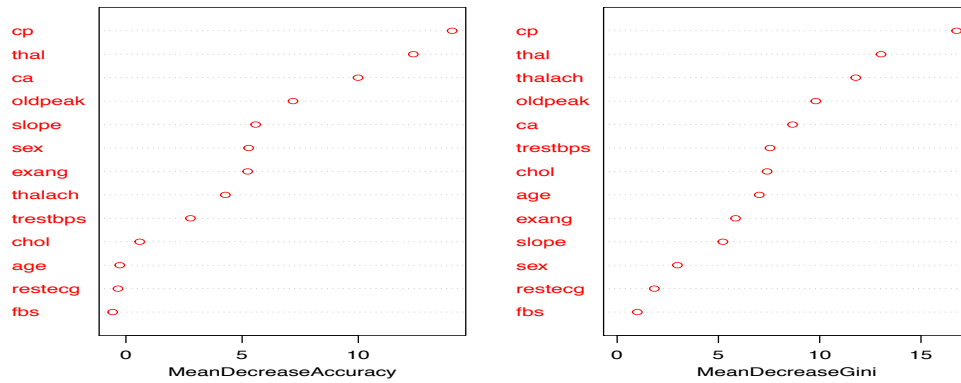

Figure 5.2: Variable importance plot using Random Forest model for Heart-Disease data.

(C) in order to obtain the best predictive model with optimal cost. The highest accuracy is achieved when  $\gamma$  is 0.01 for diabetes dataset and 0.1 for heart disease dataset. Table 5.3 summarizes the prediction mean square error (PMSE) for the predicted probabilities and miss-classification rate (MCR) for both diabetes and heart disease datasets.

Table 5.3: **Model Evaluation**

Models	Diabetes Dataset		Heart Disease Dataset	
	PMSE	MCR	PMSE	MCR
LGR- $L_1$	0.173	0.256	0.151	0.172
RGR	0.174	0.264	0.149	0.193
PCR	0.194	0.308	0.107	0.118
RF	0.169	0.252	0.145	0.172
SVM	0.169	0.240	0.144	0.162

### 5.1.2 Model Evaluation

This subsection presents the accuracy of our predictive models obtained from above analysis. Tables 5.4 & 5.5 show the sensitivity, specificity, accuracy and confidence interval with 95% significance level for both diabetes and heart disease data. The sensitivity of models measures the proportion of people with the disease (diabetes and heart disease) who will have a positive result. So the highly sensitive test is one that correctly identifies patients with a disease. For example, the Logistic regression ( $L_1$ ) test is 75.81% sensitive for diabetes data, that is, the model classifies 75 individuals out of every 100 patient correctly who have the diabetes (see Table 5.4). On the other hand, the specificity measures the proportion of people without the disease (diabetes or heart disease) who will have a negative result. For instance, the logistic regression ( $L_1$ ) for diabetes test is 70.31% specific, meaning that the model identifies 70% of individuals correctly who do not have the diabetes (see Table 5.4). We plotted the ROC curves between True Positive Rate ( $Y$ -axis) and False Positive Rate

( $X$ -axis) of our predictive models in Figs. 5.3 and 5.4. In these figures, the diagonal line represents the threshold (0.5) of ROC curves. The areas under the curve are almost 0.8 for all models fitted with diabetes data. For heart disease data, the area under the ROC curve is 0.942 for principal component regression. Thus it is concluded that ML techniques have good predictive ability on diabetes and heart disease data.

Table 5.4: Model Evaluation using ROC Curve for Diabetes data.

Models	Sensitivity (%)	Specificity (%)	Accuracy (%)	Conf. Interval (%)
LGR-L <sub>1</sub>	75.81	70.31	74.44	(68.52 - 79.69)
RGR	85.19	60.87	74.00	(68.10 - 79.32)
PCR	87.50	40.00	70.40	(64.32 - 75.99)
RF	86.25	54.44	74.80	(68.94 - 80.06)
SVM	79.41	68.75	76.00	(70.21 - 81.16)

Table 5.5: Model Evaluation using ROC Curve for Heart Disease data.

Models	Sensitivity (%)	Specificity (%)	Accuracy (%)	Conf. Interval (%)
LGR-L <sub>1</sub>	77.36	90.00	82.20	(73.57 - 89.83)
RGR	91.11	72.92	81.72	(72.35 - 88.92)
PCR	95.56	81.25	88.17	(79.82 - 93.95)
RF	78.43	88.10	82.80	(73.57 - 89.83)
SVM	78.00	86.05	81.72	(72.35 - 88.98)

# Chapter 6

## Concluding remarks

The dissertation deals with the predicting stochastic volatility for extreme fluctuations of high frequency data arising in finance and geophysics. As the high frequency data appears very quickly, the fluctuations of these data contain specific reasons for the dynamics of data. In chapter 1, it is shown that the deterministic model does not encapsulate the full evolution of volatility and some volatility models can not capture the financial crashes or extreme fluctuations of seismic events. The deterministic approach often does not allow the level of conservatism present to be quantified, often leading to over-conservatism or inadvertent non-conservatism. In this case, a type of stochastic volatility models that incorporates time-varying parameters are implemented with stationary conditions at different levels. The stationary process is relatively easy to model the high frequency time series and facilitates prediction with higher accuracy and fidelity.

The SV model is used with a kalman filtering technique to estimate the parameters and standard errors. The kalman filtering is advantageous as it filters out unnecessary information (noise) in the high frequency data. The MLE is computed to find the optimal estimation of time-varying parameters in order to forecast the data volatility. The aims of this research focused on analyzing three volatility models: the GARCH, the APARCH, and the SV models in order to predict data volatility.

The parameter estimates of the GARCH (1, 1) and APARCH models indicate that there exists a stationary solution in the conditional volatility of high frequency financial returns (see subsections 4.1.1 and 4.1.2). But for the SV model, we were able to estimate the volatility parameters of time series including extreme fluctuations. It is because the one-step-ahead predictions along with the estimated standard error of stochastic volatility

model do not show any limitations unlike the GARCH and APARCH models. We notice that the APARCH model is able to solve the leverage effect of GARCH model. But the GARCH and the APRACH both are more sensitive to noise or unexpected shocks compared to stochastic volatility model. The reason is that the SV model takes into account a stochastic component of the data volatility and estimates the time-varying parameters using filtering techniques. The estimates obtained from SV model are stable around the true value. In Figs. 4.1-4.2, it is clear that the stochastic volatility is able to detect the financial crashes or extreme fluctuations for both financial and geophysical data.

From data background, it is observed that there are some noisy observations like the values of zeroes in high frequency data which do not fit with the stochastic volatility model. A new approach has been developed in order to fit the SV model with noisy data. In this case, a stochastic differential equation has been used to first simulate the high frequency data. We used the superposed Ornstein-Uhlenbeck model with the Lévy driven process and simulated data via the solution of the stochastic differential equation. The high frequency data aligns with this technique because of its stochastic behavior. The low estimated errors (see Table 4.11) implies that the estimation procedure is accurate and capable of generating a higher forecasting accuracy.

## 6.1 Future works

The summary of this work opens avenues for predicting the other high frequency data like volcanic eruptions data, atmospheric data, other seismic events and financial crashes data using SV models. For the noisy part of data, other types of simulation technique may be applied, for example, systems of stochastic differential equations, machine learning and deep learning algorithms. As we know, the high frequency data follow almost log-normal distribution, for any finite-variance Lévy process, randomizing time is equivalent to randomizing variance. Thus, the time-varying Lévy process generates stochastic volatility (SV) by randomizing time, which may improve the forecasting performance. The methodologies

can be used for market analysis, portfolio design or applied in other disciplines such as geophysics, social sciences, medicine and other public health datasets. In particular, the machine learning algorithms can be applied to analyze the novel COVID-19 disease.

# Curriculum Vitae

Md Al Masum Bhuiyan was born on January 19. Currently, he is pursuing a Ph.D. degree in Computational Science at The University of Texas at El Paso (UTEP). He is also enrolled in the Big Data Analytics Graduate Certificate program at UTEP. He received a Master degree in Mathematical Sciences at UTEP in 2015.

He earned another Master degree in Applied Mathematics and, prior to that, a Bachelor degree in Mathematics, both from University of Dhaka, one of the top ranked universities for scientific research in Bangladesh. This fuelled his interest in pursuing the doctoral degree in Computational Science Program (CPS), where he excels at theoretical, statistical, and numerical problem-solving abilities, as well as programming skills.

His research focuses on high frequency and high dimensional data analysis and other data analytics applications using statistical methods, stochastic differential equation, stochastic volatility and machine learning algorithms. While pursuing the Ph.D. in CPS, he worked as a Teaching Assistant, Research Assistant, MATH instructor, and Math Adjunct faculty of El Paso Community College as internship programs.

He has several publications, as well as several paper presentations at national and international conferences. He received several scholarships from UTEP, several travel funds from different Universities and a scholar award in the category of outstanding performance of research presentation. Recently the UTEP, the El Paso Herald, the News-wise magazine published articles in their websites on his excellent research achievements.

He served as a reviewer of several scientific journals, judge of several science-fairs and symposiums and as a treasurer of Computational Science Student Association in 2018-2019. He is a member of SIAM, AMS and ASA associations.

Residential address: 300, W Nevada Ave, Apt-01
